Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Preface

Few fields in medicine have grown, evolved, and changed as rapidly as critical care medicine has during the past 40 years. From its origins in the postoperative recovery room and the coronary care unit, the modern intensive care unit (ICU) now represents the ultimate example of medicine's ability to supply the specialized personnel and technology necessary to sustain and restore seriously ill persons to productive lives. While the field continues to evolve rapidly, sufficient principles, knowledge, and experience have accumulated in the past few decades to warrant the production of a textbook dedicated to adult critical care medicine. We chose to limit the subject matter of our book to the critical care of *adult* patients to allow the production of a comprehensive textbook in a single volume.

This book was envisioned to be multidisciplinary and multiauthored by acknowledged leaders in the field but aimed primarily at practicing critical care physicians who spend the better part of their time caring for patients in an ICU. Thus, the book would be appropriate for critical care internists as well as for surgical or anesthesia critical care specialists. The goal was to produce the acknowledged "best practice" standard in critical care medicine.

The first edition of the textbook was published in 1995, co-edited by Joe Parrillo and Roger Bone. The book sold exceedingly well for a first edition text. After the untimely death of Roger Bone in 1997, Phil Dellinger joined Joe Parrillo as the co-editor for the second, third, and now this fourth edition. As co-editors, we have labored to produce a highly readable text that can serve equally well for comprehensive review and as a reference source. We felt that it was important for usability and accessibility to keep the book to a single volume. This was a challenge, because critical care knowledge and technology have expanded significantly during the past decade. By placing emphasis on clear, concise writing and keeping the focus on critical care medicine for the adult, this goal was achieved.

Our view of critical care medicine is mirrored in the organization of the textbook. Modern critical care is a multidisciplinary specialty that includes much of the knowledge and technology contained in many disciplines represented by the classic organ-based subspecialties of medicine, as well as the specialties of surgery and anesthesiology. The book begins with a section consisting of chapters on the technology, procedures, and pharmacology that are essential to the practicing critical care physician. This section is followed by sections devoted to the critical care aspects of

cardiovascular, pulmonary, infectious, renal, metabolic, neurologic, gastrointestinal, and hematologic-oncologic diseases. Subsequent chapters are devoted to important social, ethical, and other issues such as psychiatric disorders, severity of illness scoring systems, and administrative issues in the ICU. This fourth edition has significant content additions and revisions, including a new chapter devoted to bedside ICU ultrasound. Online videos are also available featuring a variety of content areas, including echocardiograms and bedside ultrasounds of a variety of exam sites.

Each chapter is designed to provide a comprehensive review of pertinent clinical, diagnostic, and management issues. This is primarily a clinical text, so the emphasis is on considerations important to the practicing critical care physician; also presented, however, are the scientific (physiologic, biochemical, and molecular biologic) data pertinent to the pathophysiology and management issues. We have aimed for a textbook length that is comprehensive but manageable. Substantial references (most now online) are provided for readers wishing to explore subjects in greater detail. We have identified key points and key references to highlight the most important issues within each chapter. Continued popular features of this fourth edition include a color-enhanced design and clinically useful management algorithms.

We have been fortunate to attract a truly exceptional group of authors to write the chapters for *Critical Care Medicine: Principles of Diagnosis and Management in the Adult*. For each chapter, we have chosen a seasoned clinician-scientist actively involved in critical care who is one of a handful of recognized experts on his or her chapter topic. We have continued the international flavor of our authorship. To provide uniformity in content and style, one or both of us have edited and revised each chapter.

We wish to thank the highly dedicated people who provided us with the assistance needed to complete a venture of this magnitude. Our thanks go to Linda Rizzuto, who provided valuable organizational and editorial input; to Ellen Lawlor, for her administrative assistance; and to the excellent editorial staff at Elsevier, including William Schmitt, Janice Gaillard, and Sharon Corell.

Neurologic Prognostication

EPIDEMIOLOGY AND GENERAL PRINCIPLES

Sudden cardiac arrest is defined as the cessation of effective cardiac mechanical activity as confirmed by the absence of signs of circulation. Sudden cardiac arrest is the most common fatal manifestation of cardiovascular disease and a leading cause of death worldwide. In North America alone, approximately 350,000 persons annually undergo resuscitation for sudden cardiac arrest. Approximately 25% of sudden cardiac arrest events are due to pulseless ventricular arrhythmias (i.e., ventricular fibrillation [VF] or pulseless ventricular tachycardia [VT]), whereas the rest can be attributed to other cardiac rhythms (i.e., asystole or pulseless electrical activity [PEA]).¹ Patients who suffer cardiac arrest due to VF or VT have a much higher chance of surviving the event compared with patients who present with PEA/asystole.² Patients with ventricular arrhythmias have a better prognosis because (1) ventricular arrhythmias are potentially treatable with defibrillation (i.e., “shockable” initial rhythm) to restore circulation, whereas the other initial rhythms are not, and (2) ventricular arrhythmias are typically a manifestation of a cardiac cause of cardiac arrest (e.g., acute myocardial infarction), whereas the other initial rhythms are more likely to be related to a noncardiac cause and perhaps an underlying condition that is less treatable. The success with cardiopulmonary resuscitation (CPR) for VF as compared to other rhythms across varying levels of rescuer intervention is displayed in [Table 1.1](#). The basic principles of resuscitation are an integral part of training for many health care providers (HCPs). Because timely interventions for cardiac arrest victims have the potential to

be truly lifesaving, it is especially important for critical care practitioners to have a sound understanding of the evaluation and management of cardiac arrest.

A number of critical actions (chain of survival) must occur in response to a cardiac arrest event. The *chain of survival* paradigm ([Fig. 1.1](#)) for the treatment of cardiac arrest has five separate and distinct elements: (1) immediate recognition that cardiac arrest has occurred and activation of the emergency response system; (2) application of effective CPR; (3) early defibrillation (if applicable); (4) advanced cardiac life support; and (5) initiation of postresuscitation care (e.g., therapeutic hypothermia).³

CARDIOPULMONARY RESUSCITATION AND ADVANCED CARDIAC LIFE SUPPORT

For CPR to be effective in restoring spontaneous circulation, it must be applied immediately at the time of cardiac arrest. Therefore, immediate recognition that a cardiac arrest has occurred and activation of the emergency response system is essential. Patients become unresponsive at the time of cardiac arrest. Agonal gasps may be observed in the early moments after a cardiac arrest event, although normal breathing ceases. Pulse checks (i.e., palpation of femoral or carotid arteries for detection of a pulse) are often unreliable, even when performed by experienced HCPs.⁴ Because delays in initiating CPR are associated with worse outcome, and prolonged attempts to detect a pulse may result in a delay in initiating CPR, prolonged pulse checks are to be avoided. CPR should be started immediately if the patient is unresponsive and either has agonal gasps or is not breathing.³

Table 1.1 Estimates of Success of Cardiopulmonary Resuscitation Based on 31 Published Reports

Intervention Category	Hospital Discharge Rate (%)	
	All Rhythms	Ventricular Fibrillation
BLS	5	12
BLS + defibrillation	10	16
ACLS	10	17
BLS + ACLS	17	26
BLS + defibrillation + ACLS	17	29

Improving survival from sudden cardiac arrest: The “chain of survival” concept. *Circulation* 1991;83:1832-1847.

Figure 1.1 The American Heart Association chain of survival paradigm. This figure represents the critical actions needed to optimize the chances of survival from cardiac arrest. The links (from left to right) include (1) immediate recognition of cardiac arrest and activation of the emergency response system; (2) early and effective cardiopulmonary resuscitation; (3) defibrillation (if applicable); (4) advanced cardiac life support; and (5) post-cardiac arrest care (including therapeutic hypothermia if appropriate). (Reprinted with permission from Travers AH, Rea TD, Bobrow BJ, et al: Part 4: CPR overview: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 2010;122(18 Suppl 3):S676-684.)

CHEST COMPRESSIONS

In CPR, chest compressions are used to circulate blood to the heart and brain until a pulse can be restored. The mechanism by which chest compressions generate cardiac output is through an increase in intrathoracic pressure plus direct compression of the heart. With the patient lying in the supine position, the rescuer applies compressions to the patient's sternum. The heel of one hand is placed over the lower half of the sternum and the heel of the other hand on top in an overlapping and parallel fashion. The recommended compression depth in adults is 2 inches. The recommended rate of compression is 100 or more per minute. “Push hard, push fast” is now the American Heart Association (AHA) mantra for CPR instruction. This underscores the importance of vigorous chest compressions in achieving return of spontaneous circulation (ROSC).⁵ In addition, incomplete recoil of the chest impairs the cardiac output that is generated, and thus the chest wall should be allowed to recoil completely between compressions. Owing to rescuer fatigue, the quality of chest compressions predictably decreases as the time providing chest compressions increases, and the persons providing chest compressions

(even experienced HCPs) may not perceive fatigue or a decrease in the quality of their compressions.⁶ Therefore, it is recommended that rescuers performing chest compressions rotate every 2 minutes.

The quality of CPR is a critical determinant of surviving a cardiac arrest event.⁷ Minimization of interruptions in chest compressions is imperative. Interruptions in chest compressions during CPR have been quite common historically, and the “hands off” time has been shown to take up a substantial amount of the total resuscitation time.⁷ Potential reasons for “hands off” time include pulse checks, rhythm analysis, switching compressors, procedures (e.g., airway placement), and pauses before defibrillation (“preshock pause”). All of these potential reasons for interruptions must be minimized. Pauses related to rotating compressors or pulse checks should take no longer than a few seconds.⁵ Eliminating (or minimizing) preshock pauses has been associated with higher likelihood of ROSC and improved clinical outcome.⁸

DEFIBRILLATION

The next critically important action in the resuscitation of patients with cardiac arrest due to pulseless ventricular arrhythmias (i.e., VF or pulseless VT) is rapid defibrillation. Delays in defibrillation are clearly deleterious, with a sharp decrease in survival as the time to defibrillation increases.⁹ With the advent of automatic external defibrillators (AEDs) and their dissemination into public places, both elements of effective CPR (both effective chest compressions and rapid defibrillation) can be performed by lay rescuers in the field for patients with out-of-hospital cardiac arrest. Figure 1.2 shows the importance of rapid defibrillation, with decreasing success of resuscitation with increasing time to defibrillation.

RESCUE BREATHING

The most recent AHA recommendations regarding ventilation during CPR depends on who the rescuer is (i.e., trained HCPs versus lay person).⁵ For trained HCPs, the recommended ventilation strategy is a cycle of 30 chest compressions to two breaths until an endotracheal tube is placed, and then continuous chest compressions with one breath every 6 to 8 seconds after the endotracheal tube is placed. Excessive ventilations can be deleterious from a hemodynamic perspective due to increased intrathoracic pressure and reduction in the cardiac output generated by CPR and thus should be avoided during resuscitation. Excessive ventilation could also potentially result in alkalemia.

For lay persons who are attempting CPR in the field for a victim of out-of-hospital cardiac arrest, rescue breathing is no longer recommended. Rather, the recommended strategy is compression-only (or “hands-only”) CPR.⁵ The rationale is that compression-only CPR can increase the number of effective chest compressions that are delivered to the patient (i.e., minimizes interruptions for rescue breaths), and does not require mouth-to-mouth contact. Mouth-to-mouth contact is one of the perceived barriers to CPR in the field. By removing this element, the hope is that an increase in attempts at bystander CPR will result. Hands-only CPR has been found to be not inferior to conventional

Figure 1.2 Relationship between the time interval before attempted defibrillation and the proportion of patients discharged from the hospital alive after out-of-hospital cardiac arrest. (Adapted from Weaver WD, Cobb LA, Hallstrom AP, et al: Factors influencing survival after out-of-hospital cardiac arrest. *J Am Coll Cardiol* 1986; 7:752-757.)

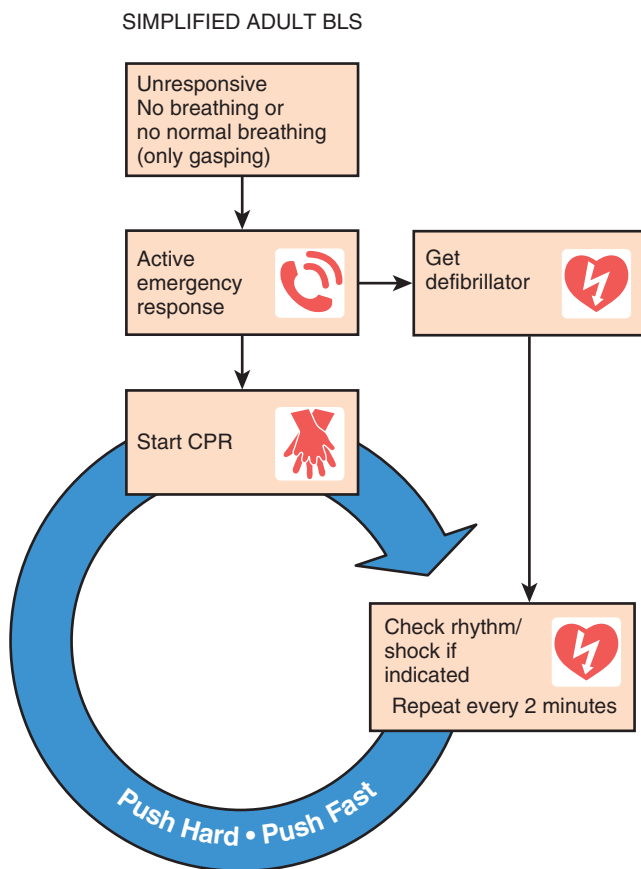

Figure 1.3 American Heart Association simplified basic life support algorithm. BLS, basic life support; CPR, cardiopulmonary resuscitation (Reprinted with permission from Berg RA, Hemphill R, Abella BS, et al: Part 5: Adult basic life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 2010;122[18 Suppl 3]:S685-705.)

CPR including rescue breaths for victims of out-of-hospital cardiac arrest,¹⁰⁻¹² and thus hands-only CPR has become the preferred technique to teach lay rescuers.

Figure 1.3 displays the AHA algorithm for adult basic life support.

ADVANCED CARDIAC LIFE SUPPORT

There are several additional elements of resuscitation that are intended specifically for trained HCPs (e.g., advanced cardiac life support [ACLS]), and these elements include pharmacologic therapy. Figure 1.4 displays the AHA algorithm for ACLS.¹³

The primary goal of pharmacologic interventions is to assist the achievement and maintenance of spontaneous circulation. The mainstay of pharmacologic interventions is vasopressor drugs. Epinephrine (1 mg) is administered by intravenous (IV) or intraosseous (IO) route every 3 to 5 minutes during CPR until ROSC is achieved.¹³ If IV/IO access cannot be established, epinephrine could be administered via endotracheal tube, but at a higher dose (2-2.5 mg). Vasopressin (40 mg IV/IO) can be substituted for the first or second dose of epinephrine. Amiodarone is the preferred antiarrhythmic agent. In patients with VF/VT not responding to CPR, defibrillation, and vasopressor therapy, amiodarone is recommended (300 mg IV/IO for the first dose, 150 mg IV/IO for the second dose).¹³ Recently, the use of atropine for PEA/asystole was removed from the ACLS algorithm. Along these lines, there is also insufficient evidence to recommend routine administration of sodium bicarbonate during CPR.

It is notable that the impact of recommended ACLS therapies on outcome from cardiac arrest remains a matter of debate. Some studies have shown that ACLS interventions did not improve clinical outcomes when compared to basic life support alone.¹⁴

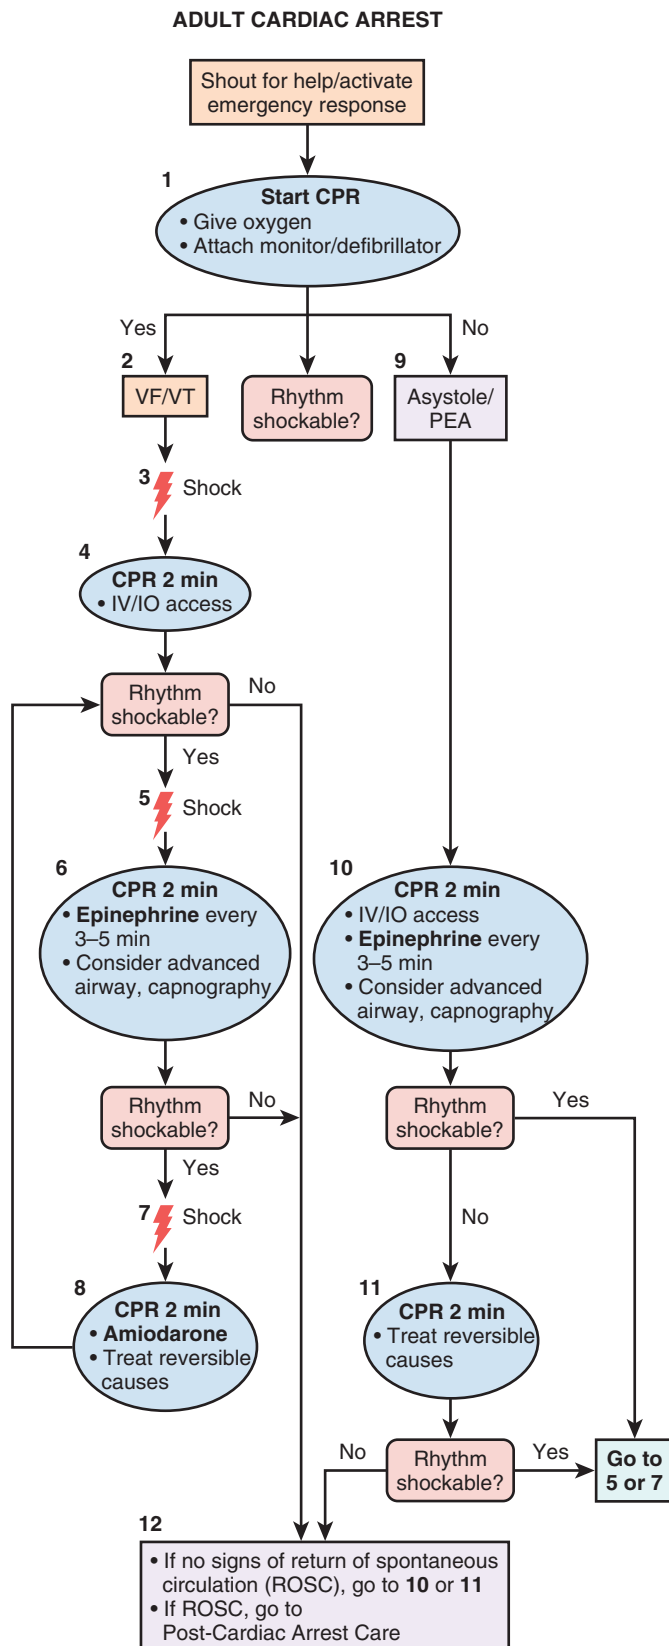

POSTRESUSCITATION CARE

Even if ROSC is achieved with CPR and defibrillation, cardiac arrest victims are at extremely high risk of dying in the hospital, and many who survive sustain permanent crippling neurologic sequelae. Approximately 50% to 60% of patients successfully resuscitated from out-of-hospital cardiac arrest do not survive. After ROSC, global ischemia/reperfusion (I/R) injury results in potentially devastating neurologic disability. The primary cause of death among postresuscitation patients is brain injury. However, clinical trials have shown that mild therapeutic hypothermia after ROSC can improve outcomes. These landmark clinical trials have dramatically transformed the classical thinking about anoxic brain injury after cardiac arrest; this condition is in fact *treatable*. Early therapeutic interventions such as hypothermia initiated in the post-ROSC period can improve the trajectory of the long-term disease course. Accordingly, the postresuscitation care is now considered to be a crucial fifth link in the chain of survival paradigm (see Fig. 1.1).¹⁵

GENERAL APPROACH

Patients resuscitated from cardiac arrest should be admitted to a critical care unit with the following capabilities:¹⁶

- Critical care support to optimize cardiovascular indices and vital organ perfusion, and prevent repeat cardiac arrest (or provide rapid treatment of rearrest if it occurs)

**CPR Quality**

- Push hard (≥ 2 inches [5 cm]) and fast (≥ 100 /min) and allow complete chest recoil
- Minimize interruptions in compressions
- Avoid excessive ventilation
- Rotate compressor every 2 minutes
- If no advanced airway, 30:2 compression-ventilation ratio
- Quantitative waveform capnography
 - If $PETCO_2 < 10$ mm Hg, attempt to improve CPR quality
- Intra-arterial pressure
 - If relaxation phase (diastolic) pressure < 20 mm Hg, attempt to improve CPR quality

Return of Spontaneous Circulation (ROSC)

- Pulse and blood pressure
- Abrupt sustained increase in $PETCO_2$ (typically ≥ 40 mm Hg)
- Spontaneous arterial pressure waves with intra-arterial monitoring

Shock Energy

- **Biphasic:** Manufacturer recommendation (e.g., initial dose of 120–200 J); if unknown, use maximum available. Second and subsequent doses should be equivalent, and higher doses may be considered
- **Monophasic:** 360 J

Drug Therapy

- **Epinephrine IV/IO Dose:** 1 mg every 3–5 minutes
- **Vasopressin IV/IO Dose:** 40 units can replace first or second dose of epinephrine
- **Amiodarone IV/IO Dose:** First dose: 300 mg bolus
Second dose: 150 mg

Advanced Airway

- Supraglottic advanced airway or endotracheal intubation
- Waveform capnography to confirm and monitor ET tube placement
- 8–10 breaths per minute with continuous chest compressions

Reversible Causes

- Hypovolemia
- Hypoxia
- Hydrogen ion (acidosis)
- Hypo-/hyperkalemia
- Hypothermia
- Tension pneumothorax
- Tamponade, cardiac
- Toxins
- Thrombosis, pulmonary
- Thrombosis, coronary

Figure 1.4 American Heart Association advanced cardiac life support (ACLS) algorithm. CPR, cardiopulmonary resuscitation; IO, intraosseous; IV, intravenous; PEA, pulseless electrical activity; ROSC, return of spontaneous circulation; VF, ventricular fibrillation; VT, ventricular tachycardia. (Reprinted with permission from Neumar RW, Otto CW, Link MS, et al: Part 8: Adult advanced cardiovascular life support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 2010;122(18 Suppl 3):S729-767.)

- Interventional cardiac catheterization for possible percutaneous coronary intervention (PCI) if needed
- Mild therapeutic hypothermia (33°–34° C) for 12 to 24 hours in attempts to prevent permanent neurologic injury
- Systematic application of an evidence-based approach to neurologic prognostication to refrain from inappropriately early final determinations of poor neurologic prognosis (i.e., prevent inappropriately early withdrawal of life support before the neurologic outcome can be known with certainty)

CRITICAL CARE SUPPORT

I/R triggers profound systemic inflammation. In clinical studies, ROSC has been associated with sharp increases in circulating cytokines and other markers of the inflammatory response. Accordingly, some investigators have referred to the post-cardiac arrest syndrome as a “sepsis-like” state. The clinical manifestations of the systemic inflammatory response may include marked hemodynamic derangements such as sustained arterial hypotension similar to septic shock. Hemodynamic instability occurs in approximately 50% of patients who survive to intensive care unit admission after ROSC, and thus the need for aggressive hemodynamic support (e.g., continuous infusion of vasoactive agents and perhaps advanced hemodynamic monitoring) should be anticipated.¹⁷

In addition to a systemic inflammatory response, an equally important contributor to post-ROSC hemodynamic instability is myocardial stunning. Severe, but potentially reversible, global myocardial dysfunction is common following ROSC. The cause is thought to be I/R injury, but treatment with defibrillation (if applied) could also contribute. Although the myocardial dysfunction occurs in the absence of an acute coronary event, myocardial ischemia may be an ongoing component of myocardial depression if an acute coronary syndrome caused the cardiac arrest. Severe myocardial stunning may last for hours but often improves by the 24-hour mark after ROSC. An echocardiogram may be helpful in hemodynamic assessment after ROSC to determine if global myocardial depression is present, as this may impact decisions on vasoactive drug support (e.g., dobutamine) or mechanical augmentation (e.g., intra-aortic balloon counterpulsation) until the myocardial function recovers. However, when needed, clinicians should be aware that β -adrenergic agents may increase the likelihood of dysrhythmia.

Although there are no data on whether specific blood pressure or other hemodynamic goals are beneficial,¹⁸ expert opinion (and clinical intuition) suggests that hemodynamics and organ perfusion should be optimized.¹⁵ Rapidly raising the blood pressure in patients who remain markedly hypotensive after ROSC is prudent, because postresuscitation arterial hypotension has been associated with sharply lower survival rate.¹⁷ Whether or not postresuscitation hypotension has a cause-and-effect relationship with worse neurologic injury or is simply a marker of the severity of the I/R injury that has occurred remains unclear.

Regarding respiratory system support, exposure to hyperoxia (excessively high partial pressure of arterial oxygen [PaO_2]) has been associated with poor clinical outcome

among adult patients resuscitated from cardiac arrest and admitted to an intensive care unit.¹⁹ These data corroborate the findings of numerous laboratory studies in animal models in which hyperoxia exposure after ROSC worsens brain histopathologic changes and neurologic function.^{20–24} A paradox may exist regarding oxygen delivery to the injured brain, where inadequate oxygen delivery can exacerbate cerebral I/R injury, but excessive oxygen delivery can accelerate formation of oxygen free radical and subsequent reperfusion injury. Although clinical data on this topic are few at the present time (and specifically no interventional studies have been performed), expert opinion advocates limiting unnecessary exposure to an excessively high postresuscitation PaO_2 by titrating the fraction of inspired oxygen down after ROSC as much as possible to maintain an arterial oxygen saturation of 94% or more.¹⁵

Seizures are not uncommon after anoxic brain injury, and it is important to be vigilant in clinical assessment for any motor responses that could represent seizure activity so that they can be treated promptly with anticonvulsant medications. Continuous electroencephalography monitoring (if available) can be useful, especially if continuous administration of neuromuscular blocking agents becomes necessary for any reason.

CARDIAC CATHETERIZATION

Acute coronary syndrome is the most common cause of sudden cardiac arrest. Clinicians should have a high clinical suspicion of acute myocardial ischemia as the inciting event for the cardiac arrest when no other obvious cause of cardiac arrest is apparent. Although ST-segment myocardial infarction is an obvious indication for PCI, other more subtle electrocardiogram abnormalities may indicate that an acute ischemic event caused the cardiac arrest. In patients with no obvious noncardiac cause of cardiac arrest, a clinical suspicion of coronary ischemia, an abnormal electrocardiogram after ROSC, and consultation with an interventional cardiologist is warranted and coronary angiography should be considered. Recent studies and experience indicate that inducing hypothermia simultaneously with emergent PCI is feasible.

THERAPEUTIC HYPOTHERMIA

Therapeutic hypothermia (TH), also called mild therapeutic hypothermia or targeted temperature management, is a treatment strategy of rapidly reducing the patient's body temperature after ROSC for the purposes of protection from neurologic injury. The body temperature is typically reduced to 33° to 34° C for 12 to 24 hours. After ROSC the severity of the reperfusion injury can be mitigated, despite the fact that the initial ischemic injury has already occurred. Reperfusion injury refers to tissue and organ system injury that occurs when circulation is restored to tissues after a period of ischemia, and is characterized by inflammatory changes and oxidative damage that are in large part a consequence of oxidative stress. Neuronal cell death after I/R injury is not instantaneous, but rather a dynamic process. In animal models of cardiac arrest, brain histopathologic changes may not be found until 24 to 72 hours after cardiac arrest.¹⁵ This indicates that a distinct therapeutic window of

Table 1.2 Therapeutic Hypothermia Versus Normothermia for Management of Comatose Survivors of Cardiac Arrest*

Outcome Measure	Patient Response: No. Affected/Total		Risk Ratio (95% CI) [†]	P Value [‡]
	Normothermia	Hypothermia		
Favorable neurologic outcome [§]	54/137 (39%)	75/136 (55%)	1.40 (1.08-1.81)	0.009
Death	76/138 (55%)	56/137 (41%)	0.74 (0.58-0.95)	0.02

*Neurologic outcome and mortality rate at 6 months in a randomized trial of therapeutic hypothermia versus normothermia in comatose survivors of out-of-hospital cardiac arrest due to ventricular fibrillation or pulseless ventricular tachycardia.

[†]The risk ratio was calculated as the rate of a favorable neurologic outcome or the rate of death in the hypothermia group divided by the rate in the normothermia group. CI, confidence interval.

[‡]Two-sided *P* values are based on Pearson's chi square tests.

[§]A favorable neurologic outcome was defined as a cerebral performance category of 1 (good recovery) or 2 (moderate disability). One patient in the normothermia group and one in the hypothermia group were lost to neurologic follow-up.

Reprinted with permission from Hypothermia After Cardiac Arrest Study Group: Mild therapeutic hypothermia to improve the neurologic outcome after cardiac arrest. *N Engl J Med* 2002;346(8):549-556.

opportunity exists. In theory, TH may protect the brain by attenuating or reversing all of the following pathophysiologic processes: disruption of cerebral energy metabolism, mitochondrial dysfunction, loss of calcium ion homeostasis, cellular excitotoxicity, oxygen free radical generation, and apoptosis. Two clinical trials of TH were published in 2002.^{25,26} These trials showed improved outcomes with TH for comatose survivors of witnessed out-of-hospital cardiac arrest with VF as the initial rhythm. The survival data for the largest of these clinical trials (i.e., the Hypothermia After Cardiac Arrest Study Group) appear in Table 1.2 and Figure 1.5.

The current AHA guidelines for CPR and emergency cardiovascular care recommend 12 to 24 hours of TH for comatose survivors of out-of-hospital cardiac arrest due to VF or pulseless VT.¹⁶ TH may also be considered for victims of in-hospital cardiac arrest and other arrest rhythms. Figure 1.6 displays the AHA algorithm for post-cardiac arrest care including TH.¹⁶

Appropriate selection of candidates for TH is clearly important. If a patient does not follow verbal commands after ROSC is achieved, this indicates that the patient is at risk for brain injury and TH should be strongly considered. If a patient is clearly following commands immediately after ROSC, then significant brain injury is less likely and it is probably reasonable to withhold TH. There are multiple potential methods for inducing TH including specialized external or intravascular cooling devices for targeted temperature management, or a combination of conventional cooling methods such as ice packs, cooling blankets, and cold (4° C) IV saline infusion. Compared to the use of specialized cooling devices, overshoot (body temperature < 31° C) is a not uncommon occurrence with use of ice packs, cooling blankets, and cold saline.²⁷ Regardless of what method is used, effective achievement of target temperature may be aided by the use of a uniform physician order set for TH induction.²⁸ The current recommendation is to maintain TH for 12 to 24 hours.¹⁶ Whether or not a longer duration of therapy could be beneficial is currently unknown.

No. at risk					
Hypothermia	137	92	86	83	11
Normothermia	138	74	66	64	9

Figure 1.5 Cumulative survival in the normothermia and hypothermia groups from a randomized trial of therapeutic hypothermia in comatose survivors of out-of-hospital cardiac arrest due to ventricular fibrillation or pulseless ventricular tachycardia. Censored data are indicated by tick marks. Shivering with TH induction is very common and should be anticipated. Shivering can be detrimental to the patient by making goal temperature more difficult (or impossible) to achieve. Therefore, immediate recognition and treatment of shivering is imperative. Adequate sedation and analgesics are an essential component of TH, especially the induction phase, and often the administration of additional sedative and opioid agents will be sufficient to ameliorate shivering. If shivering persists despite sedatives or opioid agents, neuromuscular blocking agents may be required. If neuromuscular blocking agents are used, they are often only necessary in the induction phase of TH when the temperature is dropping at a fast rate. Once target temperature is achieved, patients often stop shivering. It is prudent to try

ADULT IMMEDIATE POST-CARDIAC ARREST CARE

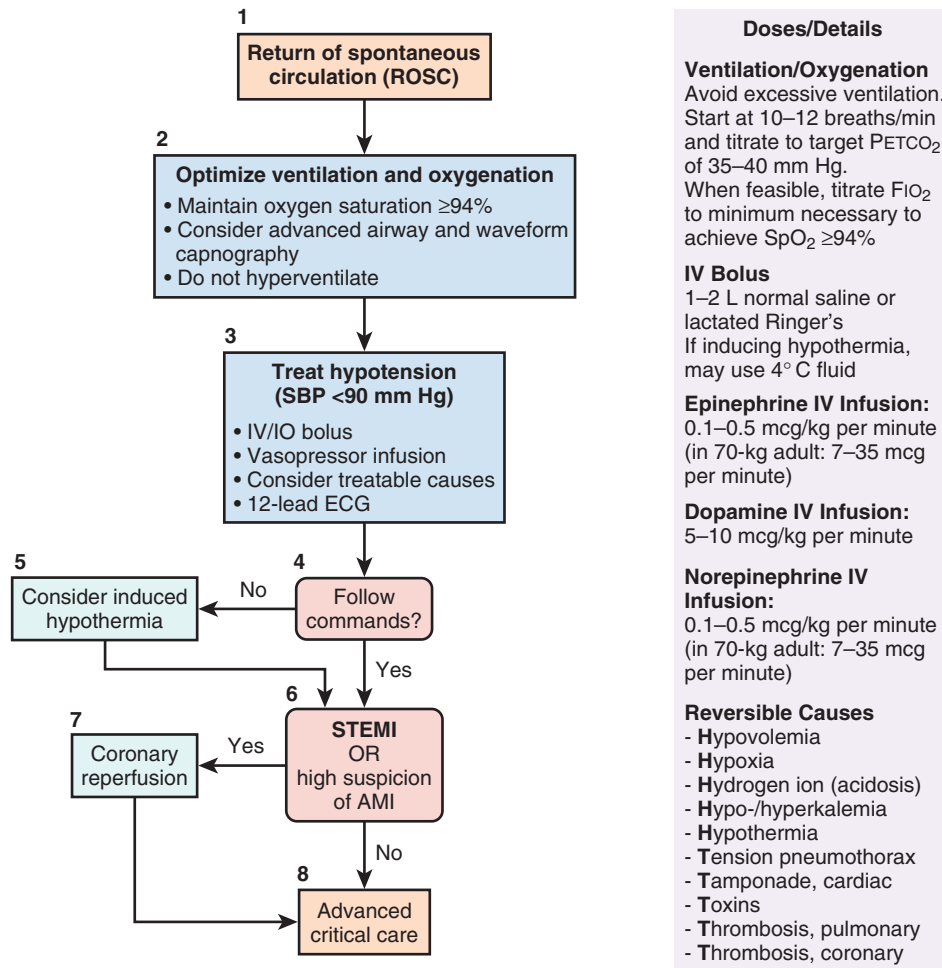

Figure 1.6 American Heart Association post-cardiac arrest care algorithm. AMI, acute myocardial infarction; ECG, electrocardiogram; IO, intraosseous; IV, intravenous; ROSC, return of spontaneous circulation; SBP, systolic blood pressure; STEMI, ST-segment elevation myocardial infarction. (Reprinted with permission from Peberdy MA, Callaway CW, Neumar RW, et al: Part 9: Post-cardiac arrest care: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care. *Circulation* 2010;122(18 Suppl 3):S768-786.)

to limit neuromuscular blocking agents to the induction phase of TH, and they likely can be withheld thereafter. Unnecessarily prolonged neuromuscular blockade should be avoided because prolonged neuromuscular weakness may persist after discontinuation and could potentially make the patient's neurologic assessment at a later time point more challenging. When using neuromuscular blocking agents for the induction of TH, their administration may be titrated to the resolution of shivering rather than complete paralysis, which may result in the administration of a much lower dose of neuromuscular blocker.

A number of potential complications are possible with TH including bradycardia, a "cold diuresis" resulting in hypovolemia and electrolyte derangements, hyperglycemia, coagulopathy, and perhaps increased risk of secondary infection. However, these potential complications are often not severe when they do occur, and in terms of risk-benefit determinations, the risk of anoxic brain injury usually greatly outweighs the risks of complications.

If TH is not initiated, fever must be avoided. Fever is not uncommon in the post-cardiac arrest population because

of the intense proinflammatory response to I/R and must be treated aggressively with antipyretic therapies and other techniques (e.g., cooling blankets). Fever is clearly detrimental in brain-injured patients because it increases cerebral metabolic rate.

NEUROLOGIC PROGNOSTICATION

Neurologic prognostication is often extremely difficult in the first few days after resuscitation from cardiac arrest.²⁹ Although some neurologic examination findings may suggest poor prognosis, few of these signs on examination are sufficiently reliable upon which to base treatment decisions (e.g., support withdrawal). These critically important decisions should hinge on neurologic examination findings in which the false-positive rate (FPR) (i.e., the rate of predicting a poor outcome that ultimately proves not to be poor) approaches zero. An abundance of clinical data exists on neurologic assessment after cardiac arrest, and few examination findings have a sufficiently low false-positive rate in the first 72 hours after ROSC to form the basis of a

limitation of support decision.^{15,30} In particular, neurologic prognostication immediately (e.g., first 24 hours) after resuscitation from cardiac arrest is especially unreliable. Among patients who are initially comatose after ROSC, one quarter to one half of patients could potentially have a favorable outcome, especially if TH is employed. In general, the recommended approach is to wait a minimum of 72 hours after ROSC before neurologic prognostication.³⁰ However, it is important to recognize that the vast majority of data on neurologic prognostication was generated before the era of TH, that is, before an effective therapy existed. In the population of patients treated with TH, the optimal time course for making neurologic prognostication may be significantly different, not only because the therapy could modulate the degree of brain injury, but also because low body temperature decreases the metabolism of sedative agents that are typically used during TH, and it may take much longer for the effects of the sedation to be eliminated. Recently published data have shown that good neurologic outcome can potentially occur even with unfavorable neurologic findings at 72 hours, suggesting that the optimal time interval to wait before attempting neurologic prognostication in the population treated with TH may be longer than 72 hours.³¹ Our general approach is to not make any final neurologic prognostication until 72 hours after ROSC. In the population treated with TH, we perform daily neurologic assessments beyond the 72-hour mark and we do not make final neurologic prognostication as long as the patient continues to improve. If there are zero signs of neurologic improvement over 2 or more consecutive days, we typically deem neurologic prognostication to be reliable at that time.

KEY POINTS

- The quality of CPR (especially in quality of and minimization of interruptions in chest compressions) is probably the single most important treatment-related determinant of outcome from cardiac arrest. Therefore, “push hard, push fast.”
- Cellular damage from ischemia/reperfusion injury is a dynamic process, and a therapeutic window exists after resuscitation from cardiac arrest in which the effects can be attenuated.

KEY POINTS (Continued)

- Therapeutic hypothermia is the first proven therapy to improve neurologic outcome after resuscitation from cardiac arrest, indicating that brain injury related to cardiac arrest is in fact a treatable condition.
- Neurologic prognostication is notoriously challenging in the early period after resuscitation from cardiac arrest, and in most cases attempts at prognostication should be withheld until at least the 72-hour mark from ROSC.

COMMON PROBLEMS IN AIRWAY MANAGEMENT

Appropriate management of the airway is the cornerstone of good resuscitation. It requires judgment (airway assessment), skill (airway maneuvers), and constant reassessment of the patient's condition. Although complex procedures sometimes are lifesaving and always carry the potential to impress, the timely use of simple airway maneuvers often is very effective and may avoid the need for further intervention.

STRUCTURE AND FUNCTION OF THE NORMAL AIRWAY

Critical care staff members require an understanding of structure and function in order to successfully manage the airway and the conditions that may affect it. The relevant information can be gained from a variety of sources.¹⁻⁵ The airway begins at the nose and oral cavity and continues

as the pharynx and larynx, which lead to the trachea (beginning at the lower edge of the cricoid cartilage) and then the bronchial tree. The airway¹ provides a pathway for airflow between the atmosphere and the lungs;² facilitates filtering, humidification, and heating of ambient air before it reaches the lower airway;³ prevents nongaseous material from entering the lower airway;⁶ and allows phonation by controlling the flow of air through the larynx and oropharynx.⁴

THE NOSE

The nose has a midline septum separating two cavities that communicate externally via the external nares (nostrils). Each cavity has a roof formed by the nasal cartilages, frontal bones, cribriform plate, ethmoid, and body of sphenoid. Portions of the maxilla and palatine bones make up the nasal floor (which also forms part of the roof of the oral

cavity). The medial wall of each nasal cavity is formed by the nasal septum, the vomer, and ethmoid bones. The lateral wall lies medial to the orbit, the ethmoid, and maxillary sinuses and has three horizontal bony projections—the superior, middle, and inferior nasal conchae. These structures greatly increase the surface area, and the overlying mucosa is highly vascular, supplied by the maxillary arterial branch of the external carotid artery and the ethmoidal branch of the ophthalmic artery. The (nonolfactory) sensory innervation of the nasal mucosa is supplied by two divisions of the trigeminal nerve.

THE ORAL CAVITY

The teeth form the lateral wall of the oral cavity, while the floor is the tongue—a mass of horizontal, vertical, and transverse muscle bundles attached to the mandible and the hyoid bone. The sulcus terminalis, a V-shaped groove, divides the anterior two thirds of the tongue (sensory innervation from the lingual nerve and taste from the chordae tympani) from the posterior one third (sensory supply from the glossopharyngeal nerve). All intrinsic and extrinsic muscles of the tongue are supplied by the hypoglossal nerve, except the palatoglossus, which is supplied by the vagus nerve.

THE PHARYNX

The adult pharynx is a midline structure, running anterior to the cervical prevertebral fascia, from the base of the skull to the level of the sixth cervical vertebra (approximately 14 cm), and continuing as the esophagus. It is a muscular tube with three portions: the nasopharynx, oropharynx, and laryngopharynx (or hypopharynx). It contains three groups of lymphoid tissue: the adenoids, the pharyngeal tonsil (on the posterior wall), and the palatine (lingual) tonsils and has the inner opening of the eustachian tube on each lateral wall. The vagus nerve supplies all but one of the pharyngeal muscles. Sensory supply is via branches of the glossopharyngeal and vagus nerves. The pharynx provides a common pathway for the upper alimentary and respiratory tracts and is concerned with swallowing and phonation.

THE LARYNX

The larynx sits anterior to the laryngopharynx and the fourth to the sixth cervical vertebrae and is posterior to the infrahyoid muscles, the deep cervical fascia, and the subcutaneous fat and skin that cover the front of the neck. Laterally lie the lobes of the thyroid gland and carotid sheath. The larynx acts as a sphincter at the upper end of the respiratory tract and is the organ of phonation. The epiglottis and the thyroid, cricoid, and paired arytenoid, cuneiform, and corniculate cartilages, together with the interconnecting ligaments, make up the skeleton of the larynx, which has a volume of 4 mL. Two pairs of parallel horizontal folds project into the lumen of the larynx—the false vocal cords (lying superiorly) and the true vocal cords (inferiorly). The opening between the true cords is called the glottis. The larynx communicates above with the laryngopharynx and below with the trachea, which begins at the lower edge of the cricoid ring.

The superior aspect of the epiglottis is innervated by the glossopharyngeal nerve, whereas the vagus, via its superior laryngeal nerve (SLN) and recurrent laryngeal nerve (RLN) branches, innervates the larynx, including the inferior surface of the epiglottis. The external (motor) branch of the SLN supplies the cricothyroid muscle, and the internal branch is the sensory supply to the larynx down to the vocal cords. The RLN supplies all of the intrinsic laryngeal muscles and is the sensory supply to the larynx below the cords. Injury to the SLN causes hoarseness secondary to a loss of tension in the ipsilateral vocal cord. Complete unilateral RLN palsy inactivates both ipsilateral adductor and abductor muscles. Vocal cord adduction, however, is maintained by the unopposed SLN-innervated cricothyroid muscle. With bilateral RLN palsy, both cords are in adduction as a result of the unopposed action of the cricothyroid muscle. On inspiration, the adducted vocal cords then act like a Venturi device, generating a negative pressure that pulls the cords together, producing inspiratory stridor—the characteristic sign of upper airway obstruction. Laryngospasm, a severe form of airway obstruction, may be triggered by mechanical stimulation of the larynx or by cord irritation due to aspiration of oral secretions, blood, or vomitus.

In health, the laryngeal abductor muscles contract early in inspiration, separating the vocal cords and facilitating airflow into the tracheobronchial tree. Movements of the thyroid and arytenoid cartilages alter the length and tension of the vocal cords, and sliding and rotational movements of the arytenoid cartilages can alter the shape of the glottic opening between the vocal cords. Fine control of the muscles producing these movements allows vocalization as air passes between the vocal cords in expiration. The sound volume is increased by resonance in the sinuses of the face and skull.

THE TRACHEOBRONCHIAL TREE

The trachea is a fibrous tube, 2 cm in diameter, running in the midline for 10 to 15 cm from the level of the sixth cervical vertebra to its bifurcation (carina) at the level of the fourth thoracic vertebra. The walls include 15 to 20 incomplete cartilaginous rings limited posteriorly by fibroelastic tissue and smooth muscle.

The cervical trachea lies anterior to the esophagus, with the RLN in the groove between the two. Anteriorly lie the cervical fascia, infrahyoid muscles, isthmus of the thyroid, and the jugular venous arch. Laterally lie the lobes of the thyroid gland and the carotid sheath. In the thorax, the trachea is traversed anteriorly by the brachiocephalic artery and vein (which may be damaged or eroded by the tracheostomy tube). To the left are the common carotid and subclavian arteries and the aortic arch. To the right are the vagus nerve, the azygos vein, and the pleurae. The carina lies anterior to the esophagus behind the bifurcation of the pulmonary trunk.

The bronchial tree is similar in structure to the trachea. Two main bronchi diverge from the carina. The right main bronchus is shorter, wider, and more vertical and runs close to the pulmonary artery and the azygos vein. The left main bronchus passes under the arch of the aorta, anterior to the esophagus, thoracic duct, and descending aorta.⁷

OVERVIEW OF AIRWAY FUNCTION

In the nose, inspired gas is filtered, humidified, and warmed before entering the lungs. Resistance to gas flow through the nose is twice that of the mouth, explaining the need to mouth-breathe during exercise when gas flows are high. Warming and humidification continue in the pharynx and tracheobronchial tree. Between the trachea and the alveolar sacs, airways divide 23 times. This network increases the cross-sectional area for the gas exchange process but also reduces the velocity of gas flow. Hairs on the nasal mucosa filter inspired air, trapping particles greater than 10 μm in diameter. Many particles settle on the nasal epithelium. Particles 2 to 10 μm in diameter fall on the mucus-covered bronchial walls (as airflow slows), initiating reflex bronchoconstriction and coughing. Ciliated columnar epithelium lines the respiratory tract from the nose to the respiratory bronchioles (except at the vocal cords). The cilia beat at a frequency of 1000 to 1500 cycles per minute, enabling them to move particles away from the lungs at a rate of 16 mm per minute. Particles less than 2 μm in diameter may reach the alveoli, where they are ingested by macrophages. If ciliary motility is defective as a result of smoking or an inherited disorder (e.g., Kartagener's syndrome or another ciliary dysmotility syndrome), the "mucus escalator" does not work, so more particles are allowed to reach the alveoli, thereby predisposing the patient to chronic pulmonary inflammation.⁸

The larynx prevents food and other foreign bodies from entering the trachea. Reflex closure of the glottic inlet occurs during swallowing⁶ and periods of increased intrathoracic (e.g., coughing, sneezing) or intra-abdominal (e.g., vomiting, micturition) pressure. In unconscious patients, these reflexes are lost, so glottic closure may not occur, increasing the risk of pulmonary aspiration.

ASSESSING ADEQUACY OF THE AIRWAY

Adequacy of the airway should be considered in four aspects:

- *Patency.* Partial or complete obstruction will compromise ventilation of the lungs and likewise gas exchange.
- *Protective reflexes.* These reflexes help maintain patency and prevent aspiration of material into the lower airways.
- *Inspired oxygen concentration.* Gas entering the pulmonary alveoli must have an appropriate oxygen concentration.
- *Respiratory drive.* A patent, secure airway is of little benefit without the movement of gas between the atmosphere and the pulmonary alveoli effected through the processes of inspiration and expiration.

PATENCY

Airway obstruction most frequently is due to reduced muscle tone, allowing the tongue to fall backward against the postpharyngeal wall, thereby blocking the airway. Loss of patency by this mechanism often occurs in an obtunded or anesthetized patient lying supine. Other causes include

the presence of blood, mucus, vomitus, or a foreign body in the lumen of the airway or edema, inflammation, swelling, or enlargement of the tissues lining or adjacent to the airway.

Upper airway obstruction has a characteristic presentation in the spontaneously breathing patient: noisy inspiration (stridor), poor expired airflow, intercostal retraction, increased respiratory distress, and paradoxical rocking movements of the thorax and abdomen.⁹ These resolve quickly if the obstruction is removed. In total airway obstruction, sounds of breathing are absent entirely, owing to complete lack of airflow through the larynx. Airway obstruction may occur in patients with an endotracheal tube (ET) or tracheostomy tube in situ due to mucous plugging or kinking of the tube or the patient's biting down on a tube placed orally. If such patients are spontaneously breathing, they will have the same symptoms and signs just described. Patients on assisted (positive-pressure) breathing modes will have high inflation pressures, decreased tidal and minute volumes, increased end-tidal carbon dioxide levels, and decreased arterial oxygen saturation.

PROTECTIVE REFLEXES

The upper airway shares a common pathway with the upper gastrointestinal tract.⁶ Protective reflexes, which exist to safeguard airway patency and to prevent foreign material from entering the lower respiratory tract, involve the epiglottis, the vocal cords, and the sensory supply to the pharynx and larynx.¹⁰ Patients who can swallow normally have intact airway reflexes, and normal speech makes absence of such reflexes unlikely. Patients with a decreased level of consciousness (LOC) should be assumed to have inadequate protective reflexes.

INSPIRED OXYGEN CONCENTRATION

Oxygen demand is elevated by the increased work of breathing associated with respiratory distress¹¹ and by the increased metabolic demands in critically ill or injured patients. Often, higher inspired oxygen concentrations are required to satisfy tissue oxygen demand and to prevent critical desaturations during maneuvers for managing the airway. A cuffed ET, connected to a supply of oxygen, is a sealed system in which the delivered oxygen concentration also is the inspired concentration. A patient wearing a facemask, however, inspires gas from the mask and surrounding ambient air. Because the patient will generate an initial inspiratory flow in the region of 30 to 60 L per minute, and the fresh gas flow to a mask is on the order of 5 to 15 L per minute, much of the tidal inspiration will be "room air" entrained from around the mask. The entrained room air is likely to dilute the concentration of oxygen inspired to less than 50%, even when 100% oxygen is delivered to the mask.¹² This unwelcome reduction in inspired oxygen concentration can be mitigated by (1) using a mask with a reservoir bag, (2) ensuring that the mask is fitted firmly to the patient's face, (3) using a high rate of oxygen flow to the mask (15 L per minute), and (4) supplying a higher oxygen concentration if not already using 100%.

RESPIRATORY DRIVE

A patent, protected airway will not produce adequate oxygenation or excretion of carbon dioxide without adequate respiratory drive. Changing arterial carbon dioxide tension (P_{CO_2}), by changing H^+ concentration in cerebrospinal fluid (CSF), stimulates the respiratory center, which in turn controls minute volume and therefore arterial P_{CO_2} (negative feedback).^{11,13} This assumes that increased respiratory drive can produce an increase in minute ventilation (increased respiratory rate or tidal volume, or both, per breath), which may not occur if respiratory mechanics are disturbed. Brain injury and drugs such as opioids, sedatives, and alcohol are direct-acting respiratory center depressants.

Ventilation can be assessed qualitatively by looking, listening, and feeling. In a spontaneously breathing patient, listening to (and feeling) air movement while looking at the extent, nature, and frequency of thoracic movement will give an impression of ventilation. These parameters may be misleading, however. Objective assessment of minute ventilation requires P_{CO_2} measurement in arterial blood or monitoring of end-tidal carbon dioxide, which can be used as a real-time measure of the adequacy of minute ventilation.¹³ If respiratory drive or minute ventilation is inadequate, positive-pressure respiratory support may be required, and any underlying factors should be addressed if possible (e.g., depressant effect of sedatives or analgesics).

MANAGEMENT OF THE AIRWAY

The aims of airway management are to provide an adequate inspired oxygen concentration; to establish a patent, secure airway; and to support ventilation if required.

PROVIDING AN ADEQUATE INSPIRED OXYGEN CONCENTRATION

Although oxygen can be administered via nasal cannula, this method does not ensure delivery of more than 30% to 40% oxygen (at most). Other disadvantages include lack of humidification of gases, patient discomfort with use of flow rates greater than 4 to 6 L per minute, and predisposition to nasal mucosal irritation and potential bleeding.¹⁴ Therefore, despite being more intrusive for patients, facemasks are superior for oxygen administration. The three main types of facemasks are shown in [Figure 2.1](#):

- The anesthesia-type facemask (mask A in [Fig. 2.1](#)) is a solid mask (with no vents) with a cushioned collar to provide a good seal. It is suitable for providing very high oxygen concentrations (approaching 100%) because entrainment is minimized and the anesthetic circuit normally includes a reservoir of gas. These masks become unacceptable for many *awake* patients within a few minutes because of the association with heat, moisture, and claustrophobia.
- The simple facemask has vents that allow heat or humidity out but that also entrain room air. These masks have no seal and are relatively loose-fitting. Such masks may have a reservoir bag (approximately 500 mL) sitting inferior to the mask (B2 in [Fig. 2.1](#)), or may have no reservoir

Figure 2.1 Facemasks: anesthesia mask (A); simple facemask (B1); simple facemask with reservoir bag (B2); Venturi mask (C).

(B1 in [Fig. 2.1](#)). Using a simple facemask, without a reservoir bag, it is difficult to deliver an inspired oxygen concentration in excess of 50% even with tight application and 100% oxygen flow to the mask. Under the same conditions, a simple mask with a reservoir bag can produce an inspired oxygen concentration of about 80%.

- The Venturi mask (C in [Fig. 2.1](#)) has vents that entrain a known proportion of ambient air when a set flow of 100% oxygen passes through a Venturi device.¹⁴ Thus, the inspired oxygen concentration (usually 24% to 35%) is known.

ESTABLISHING A PATENT AND SECURE AIRWAY

Establishing a patent and secure airway can be achieved using simple airway maneuvers, further airway adjuncts, tracheal intubation, or a surgical airway.

AIRWAY MANEUVERS

Simple airway maneuvers involve appropriate positioning, opening the airway, and keeping it open using artificial airways if needed.

Positioning for Airway Management

In the absence of any concerns about cervical spine stability (e.g., with trauma, rheumatoid arthritis, or severe osteoporosis), raising the patient's head slightly (5 to 10 cm) by means of a small pillow under the occiput can help in airway management. This adjustment extends the atlanto-occipital joint and moves the oral, pharyngeal, and laryngeal axes into better alignment, providing the best straight line to the glottis ("sniffing" position).^{15,16}

Clearing the Airway

Acute airway obstruction in the obtunded patient often due to the tongue or extraneous material—liquid (saliva, blood, gastric contents) or solid (teeth, broken dentures, food)—in the pharynx. In the supine position, secretions usually are cleared under direct vision using a laryngoscope and a rigid suction catheter.¹⁷ In some cases, a flexible suction catheter, introduced through the nose and nasopharynx, may be the best means of clearing the airway. A finger sweep

Figure 2.2 Artificial airways: oropharyngeal airway (OPA); nasopharyngeal airway (NPA); laryngeal mask airway (LMA).

of the pharynx may be used to detect and remove larger solid material in unconscious patients without an intact gag reflex. During all airway interventions, if cervical spine instability cannot be ruled out, relative movement of the cervical vertebrae must be prevented—most often by manual inline immobilization.^{17,18}

Triple Airway Maneuver

The triple airway maneuver often is beneficial in obtunded patients if it is not contraindicated by concerns about cervical spine instability. As indicated by its name, this maneuver has three components: head tilt (neck extension), jaw thrust (pulling the mandible forward), and mouth opening.¹⁹ The operator stands behind and above the patient's head. Then the maneuver is performed as follows:

- Extend the patient's neck with the operator's hands on both sides of the mandible.
- Elevate the mandible with the fingers of both hands, thereby lifting the base of the tongue away from the posterior pharyngeal wall.
- Open the mouth by pressing caudally on the anterior mandible with the thumbs or forefingers.

Artificial Airways

If the triple airway maneuver or any of its elements reduces airway obstruction, the benefit can be maintained for a prolonged period by introducing an artificial airway into the pharynx between the tongue and the posterior pharyngeal wall (Fig. 2.2).

The oropharyngeal airway (OPA) is the most commonly used artificial airway. Simple to insert, it is used temporarily to help facilitate oxygenation or ventilation before tracheal intubation. The OPA should be inserted with the convex side toward the tongue and then rotated through 180 degrees. Care must be taken to avoid pushing the tongue posteriorly, thereby worsening the obstruction. The nasopharyngeal airway (NPA) has the same indications as for the OPA but significantly more contraindications²⁰ (Box 2.1). It is better tolerated than the OPA, making it useful in semi-conscious patients in whom the gag reflex is partially

Box 2.1 Contraindications to Insertion of Oropharyngeal and Nasopharyngeal Airways

Contraindications to Oropharyngeal Airways

Inability to tolerate (gagging, vomiting)
Airway swelling (burns, toxic gases, infection)
Bleeding into the upper airway
Absence of pharyngeal or laryngeal reflexes
Impaired mouth opening (e.g., with trismus or temporomandibular joint dysfunction)

Contraindications to Nasopharyngeal Airways

Narrow nasal airway in young children
Blocked or narrow nasal passages in adults
Airway swelling (burns, toxic gases, infection)
Bleeding into the upper airway
Absence of pharyngeal or laryngeal reflexes
Fractures of the midface or base of skull
Clinical scenarios in which nasal hemorrhage would be disastrous

preserved. These artificial airways should be considered to be a temporary adjunct—to be replaced with a more secure airway if the patient fails to improve rapidly to the point at which an artificial airway no longer is needed. Such airways should not be used in association with *prolonged* positive-pressure ventilation.

ADVANCED AIRWAY ADJUNCTS

Advanced airway adjuncts fill the gap between simple airway maneuvers and the insertion of a tracheal tube or surgical airway. These devices can be used to facilitate safe reliable airway management and manual ventilation in the prehospital or emergency resuscitation setting, often without expert medical presence.

The laryngeal mask airway (LMA) is a small latex mask mounted on a hollow plastic tube.²¹⁻²⁶ It is placed “blindly” in the lower pharynx overlying the glottis. The inflatable cuff helps wedge the mask in the hypopharynx, sitting obliquely over the laryngeal inlet. Although the LMA produces a seal that will allow ventilation with gentle positive pressure, it does not definitively protect the airway from aspiration. Indications for use of the LMA in critical care are (1) as an alternative to other artificial airways, (2) the difficult airway, particularly the “can’t intubate—can’t ventilate” scenario, and (3) as a conduit for bronchoscopy. It is possible to pass a 6.0-mm ET through a standard LMA into the trachea, but the LMA must be left in situ. The intubating LMA (ILMA), which was developed specifically to aid intubation with a tracheal tube, has a shorter steel tube with a wider bore, a tighter curve, and a distal silicone laryngeal cuff.²⁷⁻³⁰ A bar present near the laryngeal opening is designed to lift the epiglottis anteriorly. The ILMA allows the passage of a specially designed size 8.0 ET.

In recent years, many modified LMAs have reached clinical practice. They have been designed with the intention of promoting easier insertion, improving reliability of the laryngeal seal, and allowing safe gastric drainage of gastric fluid.

Box 2.2 Orotracheal Intubation: Indications and Relative Contraindications

Indications

Long-term correction or prevention of airway obstruction
 Securing the airway and protecting against pulmonary aspiration
 Facilitating positive-pressure ventilation
 Enabling bronchopulmonary toilet
 Optimizing access to pharynx, face, or neck at surgery

Contraindications (Relative)

Possibility of cervical spine instability
 Impaired mouth opening (e.g., trismus, temporomandibular joint dysfunction)
 Potential difficult airway
 Need for surgical immobilization of maxilla or mandible (wires, box frame)

The Combitube (esophageal-tracheal double-lumen airway) is a combined esophageal obturator and tracheal tube, usually inserted blindly.³¹⁻³⁵ Whether the “tracheal” lumen is placed in the trachea or esophagus, the Combitube will allow ventilation of the lungs and give partial protection against aspiration. The Combitube also is a potential adjunct in the “cannot intubate–cannot ventilate” situation. Disadvantages include the inability to suction the trachea when the device is sitting in its most common position (in the esophagus). Insertion also may cause trauma, and the Combitube is contraindicated in patients with known esophageal disease or injury or intact laryngeal reflexes and in persons who have ingested caustic substances.

TRACHEAL INTUBATION

If the foregoing interventions are not effective or are contraindicated, tracheal intubation is required. This modality will provide (1) a secure, potentially long-term airway; (2) a safe route to deliver positive-pressure ventilation if required; and (3) significant protection against pulmonary aspiration. *Orotracheal intubation* is the most widely used technique for clinicians practiced in direct laryngoscopy (indications and contraindications in Box 2.2). Normally, anesthesia with or without neuromuscular blockade is necessary for this procedure, which is summarized in Box 2.3.

Tracheal intubation requires lack of patient awareness (as in the unconscious state or with general anesthesia) and the abolition of protective laryngeal and pharyngeal reflexes. The drugs commonly used to achieve these states are shown in Table 2.1. Anesthesia is achieved using an intravenous induction agent, although intravenous sedatives (e.g., midazolam) theoretically may be used. Opioids often are used in conjunction with induction agents because they may reduce the cardiovascular sequelae of laryngoscopy and intubation (tachycardia and hypertension) and may contribute to the patient's unconsciousness.

Abolition of protective laryngeal and pharyngeal reflexes sometimes is achieved by inducing a deep level of unconsciousness using one or more of the aforementioned agents, followed by inhalation of high concentrations of a volatile

Box 2.3 Procedure: Orotracheal Intubation

- Position patient and induce anesthesia ± neuromuscular blockade (if needed).
- Perform manual ventilation using triple airway maneuver and oropharyngeal airway
- Hold laryngoscope handle (left hand) near the junction with blade.
- Insert the blade along the right side of the tongue—moving tongue to the left.
- Advance tip of the blade in the midline between tongue and epiglottis.
- Pull upward and along the line of the handle of the laryngoscope.
- Lift the epiglottis upward and visualize the vocal cords.
- Do *not* use the patient's teeth as a fulcrum when attempting to visualize the glottis.
- Stop advancing tube when cuff is 2 to 3 cm beyond the cords.
- Connect to a bag-valve system and pressurize it by squeezing bag.
- Inflate cuff until audible leak around tube stops.
- Check correct tube position (auscultation) and assess cuff pressure.
- Check end-tidal CO₂ trace.

Table 2.1 Drugs Used to Facilitate Tracheal Intubation

Drug	Dose (Intravenous)
Induction Agent	
Propofol	1-2.5 mg/kg
Opioids	
Fentanyl	1.0-1.5 µg/kg
Morphine	0.15 mg/kg
Nondepolarizing Agents	
Atracurium	0.4-0.5 mg/kg
Vecuronium	0.1 mg/kg
Rocuronium	0.45-0.6 mg/kg
Depolarizing Agent	
Succinylcholine (suxamethonium)	1.0-1.5 mg/kg

anesthetic agent (e.g., sevoflurane, isoflurane). This technique sometimes is used in the difficult airway scenario to obtain conditions suitable for tracheal intubation in a patient who is still breathing spontaneously.

More often, a muscle relaxant is used to abolish the protective reflexes, abduct the vocal cords, and facilitate tracheal intubation. In the elective situation, nondepolarizing neuromuscular blocking agents are used. These drugs have the disadvantage of requiring several minutes to exert their effect, during which the patient must receive ventilation via a mask, thus allowing the possibility of gastric dilation and pulmonary aspiration. In patients at high risk of the latter (e.g., nonfasting patients), a depolarizing muscle relaxant (succinylcholine) is used because it produces suitable

Box 2.4 Procedure: Nasotracheal Intubation (Blind and Under Direct Vision)

Preparation and Assessment of the Patient

1. Use a nasal decongestant such as phenylephrine to reduce bleeding.
2. Provide local anesthesia to the nasal mucosa.
3. Examine each nostril for patency and deformity.
4. Choose the most patent nostril, and use an appropriate-size ET.
5. After induction of anesthesia, position the head and neck as for oral intubation.

Blind Nasotracheal Intubation

- Keep patient breathing spontaneously.
- Insert well-lubricated ET into the nostril (concavity forward, bevel lateral).
- While passing ET along nasal floor, listen for audible breathing through the tube.
- Advance ET, rotating as needed to maintain clear breath sounds.
- ET will pass through cords, and patient may cough.
- Technique takes time, so it is not suitable for a patient experiencing desaturation.
- Do not force passage of ET, because this could cause bleeding.

Nasotracheal Intubation (Direct Vision)

- Patient may be apneic with or without relaxants.
- Gently advance ET through the nose.
- When ET tip is in oropharynx, perform laryngoscopy.
- Visualize ET in pharynx and advance toward glottis.
- Advance ET through cords into trachea, under direct vision if possible.
- Use Magill forceps if required to guide tip while advancing ET.
- Try to avoid damaging cuff if using forceps to help passage through cords.

ET, endotracheal tube.

conditions for intubation within 15 to 20 seconds, and mask ventilation is not required. Succinylcholine has several side effects—among them hyperkalemia, muscle pains, and (rarely) malignant hyperpyrexia.

Nasotracheal intubation shares the problems and contraindications associated with the NPA.²⁰ The technique usually is employed when there are relative contraindications to the oral route (e.g., anatomic abnormalities, cervical spine instability). Nasotracheal intubation may be achieved under direct vision or with use of a blind technique, either with the patient under general anesthesia or in the awake or lightly sedated patient with appropriate local anesthesia (Box 2.4). If orotracheal or nasotracheal intubation is required but cannot be achieved, then a surgical airway is required (see later).

With a need for isolation of one lung from another, a double-lumen tube (having one cuffed tracheal lumen and one cuffed bronchial lumen fused longitudinally) can be used.³⁶ The main indications are (1) to facilitate some pulmonary or thoracic surgical procedures; (2) to isolate a lung

containing contaminated fluid (e.g., in lung abscess) or blood, thereby preventing contralateral spread; and (3) to enable differential or independent lung ventilation (ILV). ILV allows each lung to be treated separately—for example, to deliver positive-pressure ventilation with high positive end-expiratory pressure (PEEP) to one lung while applying low levels of continuous positive airway pressure (CPAP) only to the other. Such a strategy may be advantageous in cases of pulmonary air leak (bronchopleural fistula, bronchial tear, or severe lung trauma) or in severe unilateral lung disease requiring ventilatory support.^{37,38}

PROVIDING VENTILATORY SUPPORT

If a patient has no (or inadequate) spontaneous ventilation, then a means of generating gas flow to the lower respiratory tract must be provided. Negative pressure, mimicking the actions of the respiratory muscles, occasionally is used in some patients who require long-term ventilation. In acute care, however, ventilation is achieved using positive pressure, which requires an unobstructed airway; in the nonintubated patient, this is best achieved by proper positioning, the triple airway maneuver, and use of an OPA or NPA. In a patient without an ET in place, particularly if some degree of airway obstruction exists, positive-pressure ventilation often will cause gastric distention and (potentially) regurgitation and pulmonary aspiration.

BAG-VALVE-MASK VENTILATION

Ventilation with a mask requires an (almost) airtight fit between mask and face. This is best achieved by firmly pressing the mask against the patient's face using the thumb and index finger (C-grip) while pulling the mandible upward toward the mask with the other three fingers. The other hand is used to squeeze the reservoir bag, generating positive pressure. Excessive pressure from the C-grip on the mask may lead to backward movement of the mandible with subsequent airway obstruction, or a tilt of the mask with leakage of gas. If a proper seal is difficult to attain, placing a hand on each side of the mask and mandible is advised, with a second person manually compressing the reservoir bag (four-handed ventilation). Bag-valve-mask systems have a self-reinflating bag, which springs back after compression, thereby drawing gas in through a port with a one-way valve. It is important to have a large reservoir bag with a continuous flow of oxygen attached to this port in order to ensure a high inspired oxygen concentration.^{39,40} Bag-valve-mask ventilation usually is a short-term measure in urgent situations or is used in preparation for tracheal intubation.

PROLONGED VENTILATION USING A SEALED TUBE IN THE TRACHEA

Ventilation of the lungs with a bag-valve-mask arrangement is difficult if required for more than a few minutes or if the patient needs to be transported. In these instances, ventilation through a sealed tube in the trachea is indicated. Orotracheal or nasotracheal intubation, surgical cricothyrotomy, and tracheostomy all achieve the same result: a cuffed tube in the trachea, allowing the use of positive-pressure ventilation and protecting the lungs from aspiration. Mechanical ventilation is discussed in Chapter 9.

APNEIC OXYGENATION

Apneic oxygenation is achieved using a narrow catheter that sits in the trachea and carries a flow of 100% oxygen. The catheter may be passed into the trachea via an ET or under direct vision through the larynx. This apparatus can be set up as a low-flow open system (gas flow rate of 5 to 8 L per minute) or as a high-pressure (jet ventilation) system⁴¹ and can be used to maintain oxygenation with a difficult airway either at intubation or at extubation (see later).

PHYSIOLOGIC SEQUELAE AND COMPLICATIONS OF TRACHEAL INTUBATION

Laryngoscopy is a noxious stimulus that, in an awake or lightly sedated patient, would provoke coughing, retching, or vomiting and laryngospasm. In clinical practice, however, laryngoscopy and tracheal intubation usually are performed after induction of anesthesia, and in emergency situations, the patient often is hypoxic and hypercarbic, with increased sympathetic nervous system activity. Thus, the physiologic effects of laryngoscopy and tracheal intubation tend to be masked.

Laryngoscopy and intubation cause an increase in circulating catecholamines and increased sympathetic nervous system activity, leading to hypertension and tachycardia. This represents an increase in myocardial work and myocardial oxygen demand, which may provoke cardiac dysrhythmias and myocardial hypoxia or ischemia. Laryngoscopy increases cerebral blood flow and intracranial pressure—particularly in patients who are hypoxic or hypercarbic at the time of intubation.⁴² This rise in intracranial pressure will be exaggerated if cerebral venous drainage is impeded by violent coughing, bucking, or breath-holding.

Coughing and laryngospasm occur frequently in patients undergoing laryngoscopy and intubation when muscle relaxation and anesthesia are inadequate. Increased bronchial smooth muscle tone, which increases airway resistance, may occur as a reflex response to laryngoscopy or may be due to the physical presence of the ET in the trachea; in its most severe form, termed bronchospasm, this increased tone causes audible wheeze and ventilatory difficulty. Increased resistance to gas flow will occur because the cross-sectional area of the ET is less than that of the airway. This difference usually is unimportant with positive-pressure ventilation but causes a significant increase in work of breathing in spontaneously breathing patients. Resistance is directly related to $1/r^4$ (where r is the radius of the ET) and will be minimized by use of a large-bore ET. Gas passing through an ET, bypassing the nasal cavity, also loses the beneficial effects of warming, humidification, and the addition of traces of nitric oxide (NO).⁴³

The effects of intubation on functional residual capacity (FRC) are complex. In patients under anesthesia, a fall in FRC is well documented. This decrease may be due to the loss of respiratory muscle tone following induction of anesthesia and the relatively unopposed effect of the elastic recoil in the lungs.⁴³ The increased resistance to gas flow due to the presence of the ET may slow expiration,

producing intrinsic PEEP (and therefore an increase in FRC) if the next inspiration begins before expiration is complete.

Laryngoscopy and intubation may cause bruising, abrasion, laceration, bleeding, or displacement or dislocation of the structures in and near the airway (e.g., lips, teeth or dental prostheses, tongue, epiglottis, vocal cords, laryngeal cartilages). Dislodged structures such as teeth or dentures may be aspirated, blocking the airway more distally. Less common complications include perforation of the airway with the potential for the development of a retropharyngeal abscess or mediastinitis. Over time, erosions due to pressure and ischemia may develop on the lips or tongue (or external nares and anterior nose in patients with a nasotracheal tube) and in the larynx or upper trachea.⁴⁴ These lesions result in a breach of the mucosa with the potential for secondary infection. In the case of the lips and tongue, such lesions are (temporarily) disfiguring and painful and may inhibit attempts to talk or swallow.

The mucosa of the upper trachea (subglottic area) is subjected to the pressure of the cuff of the ET. This pressure reduces perfusion of the tracheal mucosa and, combined with the mechanical movement of the tube (from patient head movements, nursing procedures, or rhythmic flexion with action of the ventilator), tends to cause mucosal damage and increase the risk of superficial infection. These processes may lead to ulceration of the tracheal mucosa, fibrous scarring, contraction, and ultimately stenosis, which can be a life-limiting or life-threatening problem. Although irrefutable evidence is lacking, most clinicians believe that limiting the period of orotracheal or nasotracheal intubation and reducing cuff pressures may reduce the frequency of this complication.⁴⁴

Any tube in the trachea has a significant effect on the mechanisms protecting the airway from aspiration and infection. The mucus escalator may be inhibited by mucosal injury and by the lack of warm humidified airflow over the respiratory epithelium.⁴⁵ The disruption of normal swallowing results in the pooling of saliva and other debris in the pharynx and larynx above the upper surface of the tube's inflatable cuff, which may become the source of respiratory infection if the secretions become colonized with microorganisms, or may pass beyond the cuff into the lower airways—that is, pulmonary aspiration (silent or overt).^{46,47} The former may occur as a result of (1) colonization of the gastric secretions and the regurgitation of this material up the esophagus to the pharynx or (2) transmission of microorganisms from the health care environment to the pharynx via medical equipment or the hands of hospital staff or visitors (cross-infection).^{45,47-50}

The presence of a tube traversing the larynx and sealing the trachea makes phonation impossible. The implications of this limitation for patients and their families often are ignored. If patients cannot tell caregivers about pain, nausea, or other concerns, they may become frustrated, agitated, or violent. This may result in the excessive use of sedative or psychoactive drugs, which prolong time on ventilation and stay in the intensive care unit (ICU), with the risk of infection increased accordingly.⁵¹ The inability to communicate may therefore be a real threat to patient survival. Potential solutions involve the use of letter and picture boards, “speaking valves” (with tracheostomy), laryngeal

microphones, or computer-based communication packages. The involvement and innovations of disciplines such as the speech and language center may be advantageous.

THE DIFFICULT AIRWAY

The difficult airway has been defined as “the clinical situation in which a conventionally trained anesthetist experiences difficulty with mask ventilation of the upper airway, tracheal intubation, or both.”⁵² It has been a commonly documented cause of adverse events including airway injury, hypoxic brain injury, and death under anesthesia.⁵³⁻⁵⁹ The frequency of difficulty with mask ventilation has been estimated to be between 1.4% and 7.8%,⁶⁰⁻⁶² while tracheal

intubation using direct laryngoscopy is difficult in 1.5% to 8.5% and impossible in up to 0.5% of general anesthetics.^{58,63} The incidence of failed intubation is approximately 1:2000 in the nonobstetric population and 1:300 in the obstetric population.⁶⁴ In the critical care unit, up to 20% of all critical incidents are airway related,⁶⁵⁻⁶⁷ and such incidents may occur at intubation, at extubation, or during the course of treatment (as with the acutely displaced or obstructed ET or tracheostomy tube).

RECOGNIZING THE POTENTIALLY DIFFICULT AIRWAY

Many conditions are associated with airway difficulty (Table 2.2), including anatomic abnormalities, which may result in

Table 2.2 Conditions Associated with Difficult Airway

Causative Factors	Associated Conditions/Disorders
Abnormal facial anatomy/development	Small mouth or large tongue Dental abnormality Prognathia Obesity Advanced pregnancy Acromegaly Congenital syndromes*
Inability to open mouth	Masseter muscle spasm (dental abscess) Temporomandibular joint dysfunction Facial burns Postradiotherapy fibrosis Scleroderma
Cervical immobility/abnormality	Short neck/obesity Poor cervical mobility (e.g., ankylosing spondylitis) Previous cervical spine surgery Presence of cervical collar Postradiotherapy fibrosis
Pharyngeal or laryngeal abnormality	High or anterior larynx Deep vallecula: inability to reach base of epiglottis with blade of scope Anatomic abnormality of epiglottis or hypopharynx (e.g., tumor) Subglottic stenosis
Injury	Traumatic debris Obstructing foreign bodies Basilar skull fracture Bleeding into airway or adjacent swelling/hematoma Fractured maxilla/mandible Cervical spine instability (confirmed or potential) Laryngeal fracture or disruption
Infections	Epiglottitis Abscess Croup, bronchiolitis Laryngeal papillomatosis Tetanus/trismus
Connective tissue/inflammatory disorders	Rheumatoid arthritis: temporomandibular joint or cervical spine involvement, cricoarytenoid arthritis Ankylosing spondylitis Scleroderma Sarcoidosis
Endocrine disorders	Goiter: airway compression or deviation Hypothyroidism, acromegaly: large tongue

*Visit <http://www.erlanger.org/craniofacial> and <http://www.faces-cranio.org> for specific details.

Data from Criswell JC, Parr MJA, Nolan JP: Emergency airway management in patients with cervical spine injuries. *Anaesthesia* 1994;49:900-903; and Morikawa S, Safar P, DeCarlo J: Influence of head position upon upper airway patency. *Anaesthesiology* 1961;22:265.

an unusual appearance, thereby alerting the examiner. The goal is to identify the potentially difficult airway and develop a plan to secure it. Factors including age older than 55 years, body mass index greater than 26 kg/m², presence of a beard, lack of teeth, and a history of snoring have been identified as independent variables predicting difficulty with mask ventilation—in turn associated with difficult tracheal intubation.^{61,68}

Mallampati⁶⁹ developed a grading system (subsequently modified⁶⁴) that predicted ease of tracheal intubation at direct laryngoscopy. The predictive value of the Mallampati system has been shown to be limited^{70,71} because many factors that have no influence on the Mallampati classification—mobility of head and neck, mandibular or maxillary development, dentition, compliance of neck structures, and body shape—can influence laryngeal view.^{53,66,72,73} A study of a complex system including some of these factors found the rate of difficult intubation to be 1.5%, but with a false-positive rate of 12%.⁷⁴ A risk index based on the Mallampati classification, a history of difficult intubation, and five other variables lacked sufficient sensitivity and specificity.⁷⁵ Airway management should be based on the fact that the difficult airway cannot be reliably predicted.^{76,77} This is a particularly important consideration in the critical care environment.

THE OBSTRUCTED AIRWAY

Although the most common reason for an obstructed airway in the unintubated patient is posterior displacement of the tongue in association with a depressed level of consciousness, it is the less common causes that provide the greatest challenges. It is important to elucidate the level at which the obstruction occurs and the nature of the obstructing lesion. Obstruction may be due to infection or edema (epiglottitis, pharyngeal or tonsillar abscess, mediastinal abscess), neoplasm (primary malignant or benign tumor, metastatic spread, direct extension from nearby structures), thyroid enlargement, vascular lesions, trauma, or foreign body or impacted food.^{14,78}

Airway lesions above the level of the vocal cords are considered to lie in the upper airway and commonly manifest with stridor.⁷⁹ If breathing is labored and associated with difficulty breathing at night, rather than just noisy breathing, then the narrowing probably is more than 50%. Patients with these lesions usually fall into one of two groups: (1) those who can be intubated, usually under inhalational induction, with the ENT (ear-nose-throat) surgeon immediately available to perform rigid bronchoscopy or tracheostomy if required, or (2) those who require a tracheostomy performed while under local anesthesia. In patients with midtracheal obstruction, computed tomography (CT) imaging usually is necessary to discover the exact level and nature of the obstruction and to allow planning of airway management for nonemergency clinical presentations.⁷⁹ Tracheostomy often is not beneficial because the tube may not be long enough to bypass the obstruction. In such instances, fiberoptic intubation often may be useful.⁷⁹ Lower tracheal obstruction often is due to space-occupying lesions in the mediastinum and necessitates multidisciplinary planning involving ENT, cardiothoracic surgery, anesthesia, and critical care team members.

TRAUMA AND THE AIRWAY

Airway management in the trauma victim provides additional challenges because the victim often has other life-threatening conditions and preparation time for management of the difficult airway is limited. Approximately 15% of severely injured patients have maxillofacial involvement, and 5% to 10% of patients with blunt trauma have an associated cervical spine injury (often associated with head injury).⁸⁰

Problems encountered in trauma patients include presence in the airway of debris or foreign bodies (e.g., teeth), vomitus, or regurgitated gastric contents; airway edema; tongue swelling; blood and bleeding; and fractures (maxilla and mandible). Patients must be assumed to have a full stomach (requiring bimanual cricoid pressure and a rapid-sequence induction for intubation), and many will have pulmonary aspiration before the airway is secured. An important consideration in most cases is the need to avoid movement of the cervical spine at laryngoscopy or intubation.^{17,18} Direct injury to the larynx is rare but may result in laryngeal disruption, producing progressive hoarseness and subcutaneous emphysema. Tracheal intubation, if attempted, requires great care and skill because it may cause further laryngeal disruption. With Le Fort fractures, airway obstruction or compromised respiration requiring immediate airway control is present in 25% of cases.⁸¹ Postoperative bleeding after operations to the neck (thyroid gland, carotid, larynx) may compress or displace the airway, leading to difficulty in intubation.

THE AIRWAY PRACTITIONER AND THE CLINICAL SETTING

Although airway difficulties often are due to anatomic factors as discussed, it is important to recognize that the inability to perform an airway maneuver also may be due to a practitioner's inexperience or lack of skill.⁸²⁻⁸⁷ Expert opinion and clinical evidence also identify lack of skilled assistance as a factor in airway-related adverse events.⁸⁸⁻⁹¹ As might be expected, inexperience and lack of suitable help may contribute to failure in optimizing the conditions for laryngoscopy (Box 2.5). Airway and ventilatory management performed in the prehospital setting or in the hospital but outside an operating room (OR) carries a higher frequency of adverse events and a higher mortality rate when compared with those performed using anesthesia in an OR.⁹²⁻⁹⁶ In the critical care unit, all invasive airway maneuvers are potentially difficult.⁹⁷ Positioning is more difficult

Box 2.5 Common Errors Compromising Successful Intubation

- Poor patient positioning
- Failure to ensure appropriate assistance
- Faulty light source in laryngoscope or no alternative scope
- Failure to use a longer blade in appropriate patients
- Use of inappropriate tracheal tube (size or shape)
- Lack of immediate availability of airway adjuncts

on an ICU bed than on an OR table. The airway structures may be edematous after previous laryngoscopy or presence of an ET. Neck immobility, or the need to avoid movement in a potentially unstable cervical spine, may be other contributing factors.⁹⁸⁻¹⁰⁰ Poor gas exchange in ICU patients reduces the effectiveness of preoxygenation and increases the risk of significant hypoxia before the airway is secured.¹⁰¹ Cardiovascular instability may produce hypotension or hypoperfusion, or may lead to misleading oximetry readings (including failure to record any value at all), a further confounding factor for the attending staff.^{102,103}

MANAGING THE DIFFICULT AIRWAY

Management of the difficult airway can be considered in the framework of three possible clinical scenarios with progressively increasing risks for the patient: (1) the anticipated difficult airway; (2) the unanticipated difficult airway; and (3) the difficult airway resulting in a “cannot intubate/cannot ventilate” situation.

Requirements for clinicians involved in airway management include the following:

- Expertise in recognition and assessment of the potentially difficult airway. This involves the use of the assessment techniques noted previously and a “sixth sense.”⁷⁶
- The ability to formulate a plan (with alternatives).^{52,53,104-106}
- Familiarity with algorithm(s) that outline a sequence of actions designed to maintain oxygenation, ventilation, and patient safety. The American Society of Anesthesiologists (ASA) guidelines⁵² and the composite plan from the Difficult Airway Society (DAS)¹⁰⁴ are shown in [Figures 2.3](#) and [2.4](#). The latter summarizes four airway plans (A to D), available from the DAS website (www.das.uk.com).
- The skills and experience to use a number of airway adjuncts, particularly those relevant to the unanticipated difficult airway.

THE ANTICIPATED DIFFICULT AIRWAY

The anticipated difficult airway is the “least lethal” of the three scenarios—with time to consider strategy, optimize patient status, and obtain appropriate adjuncts and personnel. The key questions are as follows:

1. Should the patient be kept awake or be anesthetized for intubation?
2. Which technique should be used for intubation?

Awake Intubation

Awake intubation is more time-consuming, requires experienced personnel, is less pleasant for the patient (compared with intubation under anesthesia), and may have to be abandoned as a result of the patient’s inability or unwillingness to cooperate. Because spontaneous breathing and pharyngeal or laryngeal muscle tone is maintained, however, it is significantly safer. The techniques available are fiberoptic and retrograde intubation. It also may be used in patients judged to be at risk for a difficult airway, whereupon an initial direct laryngoscopic view allows intubation.

Fiberoptic Intubation. Fiberoptic intubation is a technique in which a flexible endoscope with a tracheal tube loaded

Box 2.6 Indications for Fiberoptic Intubation

Anticipated difficult intubation
Avoidance of dental damage in high-risk patient
Direct laryngeal trauma
Other need for awake intubation

along its length is passed through the glottis. The tracheal tube is then pushed off the endoscope and into the trachea, and the endoscope is withdrawn. An informed patient, trained assistance, and adequate preparation time make fiberoptic intubation less stressful. The nasotracheal route is used most often and requires the use of nasal vasoconstrictors. Nebulized local anesthetic is delivered to the airway via facemask. Sedation may be given, but ideally the patient should remain breathing spontaneously and responsive to verbal commands. The procedure often is time-consuming and tends to be used in elective situations¹⁰⁷ ([Box 2.6](#)).

Retrograde Intubation. For retrograde intubation,^{108,109} local anesthesia is provided and the cricothyroid membrane is punctured by a needle through which a wire or catheter is passed upward through the vocal cords. When it reaches the pharynx, the wire is visualized, brought out through the mouth, and then used to guide the ET through the vocal cords before it is withdrawn. This technique also can be used to guide a fiberoptic scope through the vocal cords. Owing to time constraints, it is not suitable for emergency airway access and is contraindicated in any patient with an expanding neck hematoma or coagulopathy.

Intubation Under Anesthesia

It may be decided, in spite of the safety advantage of awake intubation, to anesthetize the patient before attempted intubation. Preparation of the patient, equipment, and staff is paramount ([Box 2.7](#)). Adjuncts such as those described later should be available, either to improve the chances of intubation or to provide a safe alternative airway if intubation cannot be achieved.

UNANTICIPATED AIRWAY DIFFICULTY

The unanticipated difficult airway allows only a short period to solve the problem if significant hypoxemia, hypercarbia, and hemodynamic instability are to be avoided. The patient usually is anesthetized, may be apneic, and may have received muscle relaxants, and previous initial attempt(s) at intubation may have been unsuccessful. If appropriate equipment, assistance, and experience are not immediately at hand, little time is available to obtain them. Nevertheless, it is essential to maintain oxygenation and avoid hypercarbia if possible—commonly by mask ventilation with 100% oxygen. The four-handed technique often is used.

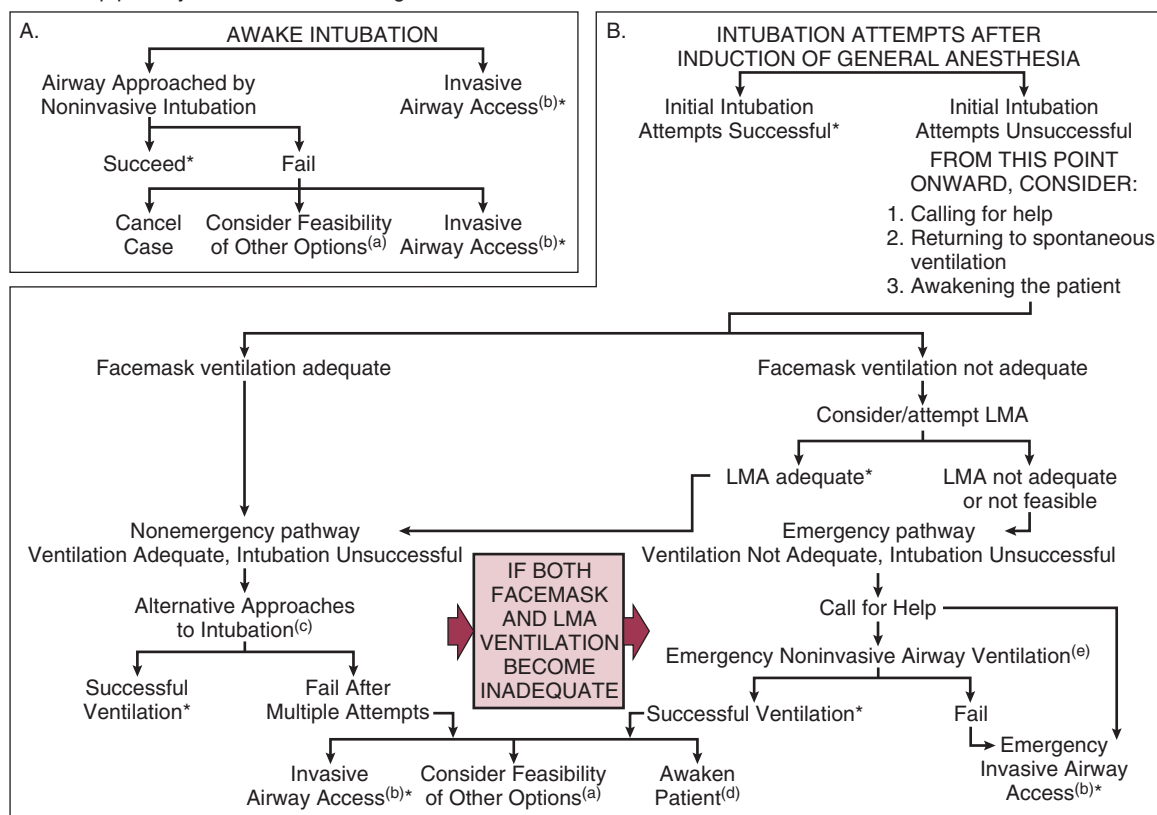

If the practitioner is inexperienced, if the patient has had no (or a relatively short-acting) muscle relaxant, and if ventilation is not a problem, it may be appropriate to let the patient recover consciousness. An awake intubation can then be planned either after a short period of recovery or on another occasion. With an experienced practitioner, it may be appropriate to continue, using techniques to

DIFFICULT AIRWAY ALGORITHM

1. Assess the likelihood and clinical impact of basic management problems:
 - Difficult ventilation
 - Difficult intubation
 - Difficulty with patient cooperation or consent
 - Difficult tracheostomy
2. Actively pursue opportunities to deliver supplemental oxygen throughout the process of difficult airway management.
3. Consider the relative merits and feasibility of basic management choices:

4. Develop primary and alternative strategies:

* Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO₂.

a. Other options include (but are not limited to) surgery utilizing face-mask or LMA anesthesia, local anesthesia infiltration, and regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy and cricothyrotomy.

c. Alternative noninvasive approaches to difficult intubation include (but are not limited to) use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or canceling surgery.

e. Options for emergency noninvasive airway ventilation include (but are not limited to) rigid bronchoscope, esophageal-tracheal Combitube ventilation, and transtracheal jet ventilation.

Figure 2.3 Algorithm for managing the difficult airway. (Adapted from Practice guidelines for management of the difficult airway: An updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anaesthesia* 2003;98:1269.)

improve the chances of visualizing and intubating the larynx. As discussed next, various adjuncts may be useful in this situation and also in the anticipated difficult airway when it has been decided to intubate with the patient under anesthesia.

Bimanual Laryngoscopy

Application of pressure on the cricoid area or the upper anterior tracheal wall, or both, by the laryngoscopist (a technique sometimes termed bimanual laryngoscopy) may improve laryngeal view.^{110,111} When the view is optimized, an

Box 2.7 Checklist for Anticipated Difficult Intubation of Patient Under General Anesthesia

- Prepare and assess the patient.
- Prepare and test the equipment.
- Ensure skilled assistance with knowledge of BURP/ bimanual laryngoscopy.
- Have available:
 - A range of tracheal tubes lubricated and cuffs tested for patency (*women*: 7.0 to 7.5 mm in internal diameter; *men*: 7.5 to 9.0 mm in internal diameter).
 - Endotracheal tube stylets
 - Laryngeal mask airway (LMA)
 - A range of laryngoscopes including specialized blades and handles
- Check battery and bulb function.
- Check functioning of suction devices.
- Use optimal patient position.
- Preoxygenation with 100% oxygen for 3 to 5 minutes if possible
- Provide other equipment as desired:
 - Gum elastic bougie*
 - Lighted stylet*
 - Combitube*
 - Intubating LMA*
 - Fiberoptic scope*

*Depending on choice of individual practitioner.
BURP, backward, upward, and rightward pressure.

assistant maintains the pressure and thus the position of the larynx, freeing the hand of the laryngoscopist to perform the intubation. The use of “blind” cricoid pressure, or BURP (backward, upward, and rightward pressure), by an assistant may impair laryngeal visualization.¹¹²⁻¹¹⁴

Stylet (“Introducer”) and Gum Elastic Bougie

The *stylet* is a smooth, malleable metal or plastic rod that is placed inside an ET to adjust the curvature—typically into a J or hockey-stick shape to allow the tip of the ET to be directed through a poorly visualized or unseen glottis.¹¹⁵ The stylet must not project beyond the end of the ET, to avoid potential laceration or perforation of the airway.

The *gum elastic bougie* is a blunt-ended, malleable rod which at direct laryngoscopy may be passed through the poorly or nonvisualized larynx by putting a J-shaped bend at the tip and passing it blind in the midline upward beyond the base of the epiglottis. Then, keeping the laryngoscope in the same position in the pharynx, the ET can be “rail-roaded” over the bougie, which is then withdrawn. For many critical care practitioners, it is the first-choice adjunct in the difficult intubation situation.^{111,116}

Different Laryngoscope or Blade

Greater than 50 types of curved and straight laryngoscope blades are available, the most commonly used being the curved Macintosh blade.²⁰ Using specific blades in certain circumstances has been both encouraged¹¹⁷⁻¹¹⁹ and discouraged.¹²⁰ In patients with a large lower jaw or “deep pharynx,” the view at laryngoscopy is often improved significantly, by using a size 4 Macintosh blade (rather than the more common adult size 3). This ensures the tip of the blade can reach the base of the vallecula to lift the epiglottis. Other

blades, such as the McCoy, may be advantageous in specific situations.^{121,122}

Lighted Stylet

A lighted stylet (light wand) is a malleable fiberoptic light source that can be passed along the lumen of an ET to facilitate blind intubation by transillumination. It allows the tracheal lumen to be distinguished from the (more posterior) esophagus on the basis of the greater intensity of light visible through anterior soft tissues of the neck as the ET passes beyond the vocal cords.¹²³ In elective anesthesia, the intubation time and failure rate with light wand–assisted intubation were similar to those with direct laryngoscopy,¹²⁴ and in a large North American survey, the light wand was the preferred alternative airway device in the difficult intubation scenario.¹²⁵ A potential disadvantage is the need for low ambient light, which may not be desirable (or easily achieved) in a critical care setting.

Video Laryngoscopy

Video laryngoscopes are intubation devices that combine modified laryngoscope blades and video technology to provide the operator with an indirect view of the glottis. Examples of video laryngoscopes include the Storz, Glidescope, McGrath, and Pentax airway scope. They are potentially useful teaching tools as they provide the operator and student with identical views.

Depending upon the manufacturer, the devices vary in design; the blades can be standard Macintosh or angulated. Video laryngoscopes with a standard Macintosh blade such as the Storz device are inserted into the oral cavity using the standard direct laryngoscope technique. After insertion, an image of the airway appears on screen. In comparison, insertion of a video laryngoscope with an angulated blade such as the Glidescope, requires insertion into the middle of the oral cavity without a tongue sweep. Once the blade tip is at the base of the tongue the device is rotated so the tip of the blade is directed at the epiglottis. A precurved stylette endotracheal tube is pushed through the glottis. The stylet is withdrawn as the ET reaches the vocal cords and the ET is advanced downward.¹²⁶ The Pentax airway scope has a video display incorporated into the handle. The transparent blade has two channels, one for the ET and the second to facilitate suctioning.¹²⁷ The McGrath laryngoscope also had a camera mounted on a blade allowing the operator to focus on the patients face and the screen simultaneously.¹²⁸

In contrast, optical laryngoscopes do not have a video attachment but instead uses a lens to provide a view of the glottis not obtained with direct laryngoscopy. The Airtraq optical laryngoscope has a blade with an optical channel and a guiding channel for the ET. It permits glottic visualization in a neutral head position.¹²⁹

Multiple controlled and observational studies suggest that video laryngoscopy can provide superior views of the glottis compared to direct laryngoscopy.^{130,131} They may be particularly useful in patients with cervical instability, either by providing a better glottic view or by a reduction in upper cervical movement during intubation.^{132,133} However, an improved laryngeal view does not always equate to a successful intubation. Intubation time can also be prolonged with the video laryngoscope, especially in

inexperienced hands.¹³⁴ The role of the video laryngoscope in the known or anticipated difficult airway is unclear. A recent meta-analysis concluded that data on these devices in the patient with a difficult airway are inadequate.¹³¹ Current data do not suggest these devices should supersede standard direct laryngoscopy for routine or difficult airways. Further research in this area is needed.

Fiberoptic Intubation

The fiberoptic bronchoscope can be used in the unanticipated difficult airway if it is readily available and the operator is skilled.^{58,135,136} With an anesthetized patient, the technique may be more difficult. Loss of muscle tone will tend to allow the epiglottis and tongue to fall back against the pharyngeal wall. This can be counteracted by lifting the mandible.

CANNOT INTUBATE–CANNOT VENTILATE

“Cannot intubate–cannot ventilate” is an uncommon but life-threatening situation best managed by adherence to an appropriate algorithm.^{52,53,104} All personnel involved will be pressured (and motivated) by the potential for severe injury to the patient. Efficient teamwork will be more likely in an environment that is relatively calm. Although it may be difficult, shouting, impatience, anger, and panic should be avoided in such situations. Figure 2.5 presents a simple flow sheet summarizing the appropriate actions.¹³⁷

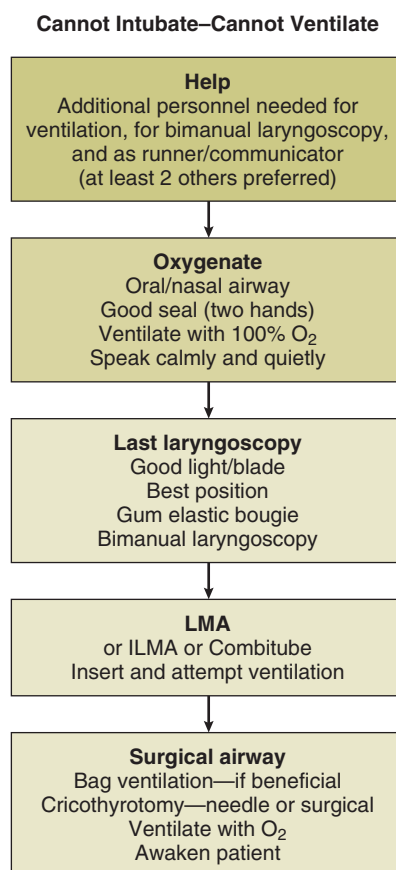

Figure 2.5 Flow chart for the “cannot intubate–cannot ventilate” scenario.

CONFIRMING TUBE POSITION IN THE TRACHEA

A critical factor in the difficult airway scenario, potentially leading to death or brain injury, is failure to recognize misplacement of the ET. Attempted intubation of the trachea may result in esophageal intubation. This alone is not life-threatening unless it goes unrecognized.¹³⁸ Thus, confirmation of ET placement in the trachea is essential.

Visualizing the ET as it passes between the vocal cords into the trachea is the definitive means of assessing correct tube positioning. This may not always be possible, however, owing to poor visualization. In addition, the laryngoscopist may be reluctant to accept that the ET is not in the trachea. Several clinical observations support the presence of the ET in the trachea.

Chest wall movement with positive-pressure ventilation (manual or mechanical) is usual but may be absent in patients with chronic obstructive pulmonary disease (COPD), obesity, or decreased compliance (e.g., in severe bronchospasm). Although condensation of water vapor in the ET suggests that the expired gas is from the lungs, this also may occur with esophageal intubation. The *absence of water vapor* usually is indicative of esophageal intubation. *Auscultation of breath sounds* (in both axillae) supports correct tube positioning but is not absolute confirmation.¹³⁹ Apparent inequality of breath sounds heard in the axillae may suggest intubation of a bronchus by an ET that has passed beyond the carina. Of note, after emergency intubation and clinical confirmation of the ET in the trachea, 15% of ETs may still be inappropriately close to the carina.¹⁴⁰

The use of capnography to detect *end-tidal carbon dioxide* is the most reliable objective method of confirming tube position and is increasingly available in critical care.¹⁴¹ False-positive results may be obtained initially when exhaled gases enter the esophagus during mask ventilation¹⁴² or when the patient is generating carbon dioxide in the gastrointestinal tract (as with recent ingestion of carbonated beverages or bicarbonate-based antacids).¹⁴³ A false-negative result (ET in trachea but no carbon dioxide gas detected) may be obtained when pulmonary blood flow is minimal, as in cardiac arrest.¹⁴⁴ Visualizing the trachea or carina through a *fiberoptic bronchoscope*, which may be readily available in critical care, also will confirm correct placement of the ET.

SURGICAL AIRWAY

The indication for a surgical airway is inability to intubate the trachea in a patient who requires it, and the techniques available are cricothyrotomy and tracheostomy.

CRICOTHYROTOMY

Cricothyrotomy may be performed as a percutaneous (needle) or open surgical procedure (Box 2.8). The indication for both these techniques is the “cannot intubate—cannot ventilate” situation. Although needle cricothyrotomy is an emergency airway procedure, the technique is similar to that for “mini-tracheostomy,” which is performed electively. Unlike the other surgical airway techniques, a needle

Box 2.8 Procedure: Needle and Surgical Cricothyrotomy

The cricothyroid membrane is diamond-shaped and lies between the thyroid and the cricoid cartilages. Inject subdermal lidocaine and epinephrine (adrenaline) for local anesthesia.

Needle Cricothyrotomy

- Identify the cricothyroid membrane and the midline.
- Insert a 14-gauge intravenous cannula and syringe through the skin and membrane.
- Continuously apply negative pressure until air enters the syringe.
- Stop at this point and push the cannula off the needle into the trachea.
- The insertion of the cannula into the trachea allows apneic (low-pressure) ventilation or jet (high-pressure) ventilation.

Surgical Cricothyrotomy

- Make a 1.5-cm skin incision over the cricothyroid membrane.
- Incise the superficial fascia and subcutaneous fat.
- Divide the cricothyroid membrane (short blade, blunt forceps, or the handle of a scalpel often is used).
- Insert (6.0) cuffed tracheostomy tube through membrane between the thyroid and cricoid cartilages.

cricothyrotomy does *not* create a definitive airway. It will not allow excretion of carbon dioxide but will produce satisfactory oxygenation for 30 to 40 minutes. It can be viewed as a form of apneic ventilation (see later discussion). There are several methods of connecting the intravenous cannula to a gas delivery circuit with the facility to ventilate, using equipment and connections readily available in the hospital. The appropriate method thus should be thought out in advance and available on the difficult airway trolley or bag. New commercial kits that come preassembled also are available.

A surgical cricothyrotomy allows a cuffed tube to be inserted through the cricothyroid membrane into the lower larynx or upper trachea. This allows positive-pressure ventilation for considerable periods and also protects against pulmonary aspiration.

TRACHEOSTOMY

A tracheostomy is an opening in the trachea—usually between the second and third tracheal rings or one space higher—that may be created surgically or made percutaneously.¹⁴⁵⁻¹⁴⁹ The indications for and contraindications to tracheostomy are summarized in Box 2.9. In comparison with long-term orotracheal or nasotracheal intubation, tracheostomy often contributes to a patient who is less agitated, requires less sedation, and who may wean from ventilation more easily.^{51,150} This increased ability to wean is sometimes attributed to reduced anatomic dead space. The potential reduction in sedation after tracheostomy, however, is a much greater advantage to weaning

Box 2.9 Tracheostomy: Indications and Contraindications

Indications for Tracheostomy

Inability to maintain a patent airway
 Suspected cervical spine instability (percutaneous technique only)
 Prevention of damage to vocal cords and (possibly) subglottic stenosis
 Abnormal anatomy (percutaneous only)
 Upper airway obstruction
 High inotrope or ventilatory requirement (relative)
 Requirement for tracheobronchial toilet with suctioning
 Part of larger surgical procedure (e.g., laryngectomy)

Contraindications to Tracheostomy

Prolonged orotracheal or nasotracheal intubation
 Local inflammation
 Failure to wean from ventilation
 Bleeding disorder (relative)
 Absence of protective airway reflexes
 Arterial bleeding in neck/upper thorax

Box 2.10 Tracheostomy: Benefits and Complications

Benefits

Comfort
 Reduced need for sedation
 Improved weaning from ventilation
 Improved ability to suction trachea
 Prevention of ulceration of lips and tongue or healing of such ulcers
 Reduced upper airway injury
 Potential for speech and oral nutrition

Complications

Misplacement of tube
 Primary hemorrhage
 Pneumothorax or tension pneumothorax; hemothorax
 Surgical emphysema
 Infection
 Late hemorrhage—erosion of innominate (or other) vessels
 Tracheoesophageal fistula

than the small reduction in dead space. The benefits and complications of tracheostomy are listed in [Box 2.10](#). Percutaneous tracheostomy is becoming increasingly common and typically is carried out by medical staff in the ICU ([Box 2.11](#)).

Another technique involving retrograde (inside-out) intubation of the trachea has been developed: A specially designed tracheal tube is used to keep the neck tissues under tension until tube placement has been accomplished.¹⁴⁷ It is a more time-consuming technique that at present is not widely practiced.

Box 2.11 Procedure: Bronchoscopy-Assisted Percutaneous Tracheostomy

- Withdraw endotracheal tube (ET) until the cuff lies at or just below the cords.
- Pass a flexible bronchoscope down ET to distal end.
- Make a 1.5- to 2-cm transverse incision at midpoint between cricoid cartilage and suprasternal notch.
- Strip away tissue down to pretracheal fascia using blunt dissection (forceps).
- Under direct vision, use a 14-gauge cannula to puncture anterior tracheal wall (in midline).
- Advance cannula into trachea, aspirate air, and insert Seldinger guidewire.
- Dilate around guidewire using dilator(s) or special forceps.
- Pass tracheostomy tube over guidewire into trachea.
- Pass bronchoscope through tracheostomy to check position.

Although no consensus exists on what defines prolonged tracheal intubation, or when tracheostomy should be performed,¹⁵¹ most ICUs convert the intubated airway to a tracheostomy after 1 to 3 weeks, with earlier tracheostomy becoming increasingly favored.^{150,151}

Conventional wisdom states that the tracheostomy procedure is more complex and time-consuming than a surgical cricothyrotomy and should be performed only by a surgeon.¹⁵² Studies in the elective ICU situation suggest that cricothyrotomy is simpler and (at worst) has a similar complication rate.^{153,154} Although needle cricothyrotomy has long been advocated as a life-saving emergency intervention,¹⁵⁵ recent work suggests that surgical cricothyrotomy is the more advantageous procedure.¹⁵⁶ In patients with unfavorable anatomy, surgical cricothyrotomy is a viable alternative to elective tracheostomy.¹⁵³ Surgical cricothyrotomy has been viewed as a temporary airway that should be converted to tracheostomy within a few days, but it may be used successfully as a definitive (medium-term) airway,^{157,158} thereby avoiding conversion from cricothyrotomy to tracheostomy, which can cause significant morbidity.^{159,160}

EXTUBATION IN THE DIFFICULT AIRWAY PATIENT (DECANNULATION)

The patient with a difficult airway still poses a problem at extubation, because reintubation (if required) may be even more difficult than the original procedure. Between 4% and 12% of surgical ICU patients require reintubation¹⁶¹ and may be hypoxic, distressed, and uncooperative at the time of reintubation. The presence of multiple risk factors for difficult intubation,¹⁰⁰ as well as acute factors such as airway edema and pharyngeal blood and secretions, makes reestablishing the airway in such patients challenging. Before extubation of any critical care patient, the critical care team should have formulated a strategy that includes a plan for reintubation.

Stylets (airway exchange catheters) that allow gas exchange either by jet ventilation or by insufflation of oxygen may be useful in extubating the difficult airway patient.^{53,162,163} The stylet is placed through the ET, with care taken to ensure that the distal end has not reached as far as the carina. The ET can then be removed after a successful leak test. The stylet may remain in situ until the situation is judged to be stable.¹⁰⁰

TUBE DISPLACEMENT IN THE CRITICAL CARE UNIT

ENDOTRACHEAL TUBE

ET displacement in the ICU is a life-threatening emergency that may result in significant morbidity.¹⁶⁴ Although tube dislodgement sometimes is viewed as unavoidable, often preventable factors are involved.¹⁶⁵⁻¹⁶⁷ Changes in patient posture or head position cause significant movement of the tube within the trachea.^{168,169} The frequency of tube displacement can be reduced by good medical and nursing practice,¹⁷⁰ attention to the arrangements and ergonomics around the bed, achieving appropriate sedation levels, and ensuring adequate ICU nurse staffing.^{171,172} Experience and the ability to anticipate possible glitches constitute an important part of prevention. The management of ET displacement starts with an assessment of whether the patient can manage without the ET.¹⁶⁷ If replacement is required, preparations for a potentially difficult reintubation are indicated.

TRACHEOSTOMY TUBE

Adverse events with tracheostomy tubes are quite common.^{167,173} Displacement may be a life-threatening event,¹⁷⁴ especially if the tube has been in place less than 5 to 7 days¹⁵¹ (before a well-defined tract between skin and trachea is formed) or if the procedure has been performed percutaneously (so that the external opening of the tract may not easily admit a new tube of the same size). The option to leave the patient without a tube should be considered, and if this option is pursued, the tracheostomy opening should be dressed to make it (to some degree) “airtight”—thus facilitating effective coughing. If the patient needs a tube but replacing the tracheostomy is not possible, then oral reintubation should be performed, after which the tracheostomy should be dressed. With a more mature tracheostomy (more than 7 days old), it usually is possible to insert a new tube through the mature tract between skin and trachea.¹⁵¹

Tracheostomy tubes may be displaced from the lumen of the trachea but appear to be normal when viewed externally. Difficulty with breathing, ventilation, or tracheal suctioning or the presence of a pneumothorax, pneumomediastinum, or surgical emphysema may be due to tracheostomy tube displacement. Fiberoptic assessment of the tube position and patency may be very useful. Assessing tracheostomy tube position on the chest x-ray film is of no value.

Box 2.12 Predictors for Poor Airway Outcomes

- Use of a supraglottic airway (only) in patients with a recognized airway difficulty
- Cases in which awake fiberoptic intubation was indicated, but not used
- Failure to use capnography or failure to interpret capnography trace correctly
- Airway maneuvers in obese patients, in the emergency department or the intensive care unit
- Use of emergency cannula cricothyrotomy (60% failure rate)
- Displacement of a tracheostomy tube
- Events related to emergence, recovery, and extubation

From Cook TM, Woodall N, Frerk C (eds): The NAP4 report: Major complications of airway management in the UK: Results of the Fourth National Audit Project of the Royal College of Anaesthetists and the Difficult Airway Society. *Br J Anaesth* 2011;106:617-631. Available at <http://www.rcoa.ac.uk/index.asp?PageID=1089>. Accessed 30 March 2011.

THE NAP4 PROJECT

The Royal College of Anaesthetists (UK) national audit project (NAP4) provided significant insight into contemporary airway management.¹⁷⁵ The project, using a 2-week national sample, estimated that approximately 2.9 million general anesthetics are administered in the United Kingdom's National Health Service (NHS) each year. Airway management involved a supraglottic airway device (SAD) in 56% of cases, a tracheal tube in 38%, and a facemask in 5%.

The study looked at airway complications during anesthesia and also in airway management in emergency departments and ICUs across the NHS hospital system. There were 16 deaths associated with the 2.9 million anesthetics and an additional 108 patients who suffered severe or moderate harm. Airway management in the ICU and emergency department was judged to be responsible for 22 deaths with an additional 28 patients suffering severe or moderate harm.

Failure to plan (ahead) appeared to be a common causative factor in a large number of poor airway outcomes. This was sometimes due to (1) poor assessment (no recognition that there was a potential problem needing a plan), (2) failure to plan even when potential problems were recognized, and (3) failure to have alternative plan(s) (in the event that “Plan A” was not successful). Many poor outcomes are the result of repeated use of an approach that has already (sometimes repeatedly) failed.^{176,177}

NAP4 revealed a number of scenarios or patient-related factors that seemed to predispose to poor airway outcomes. These predictors are summarized in [Box 2.12](#).

COMMON PROBLEMS IN AIRWAY MANAGEMENT

PROBLEM 2.1 Ineffective (Spontaneous) Breathing Despite Artificial Airway

UNDERLYING CAUSES

1. Obstructed airway
2. Depressed respiratory drive (influence of drugs)
3. Inefficient respiratory effort (e.g., from fractured ribs or diaphragmatic injury)
4. Pulmonary pathologic process (pneumonitis, contusion, collapse, consolidation)

ACTION

Attempt to deliver 100% oxygen. Check airway. When airway obstruction has been corrected or ruled out, the patient's respiratory status should improve unless another underlying pathologic process is present. If no improvement is obtained, manually ventilate the patient. If respiratory status still fails to improve, proceed to tracheal intubation with manual or mechanical ventilation. Investigate and treat any underlying condition.

PROBLEM 2.2 Ineffective Manual Ventilation Despite Artificial Airway

POTENTIAL CAUSES

1. Obstructed airway
2. Poor seal or poor technique with mask or manual ventilation
3. Pulmonary pathologic process (pneumonitis, contusion, collapse, consolidation)

ACTION

Attempt to deliver 100% oxygen at 15 to 20 L per minute. Check and readjust airway and patient head position. When airway obstruction has been corrected or ruled out, use a two-handed approach for mask and airway, with an assistant squeezing the bag. If no improvement is obtained, check for availability of someone with more airway experience. If no such person is available, proceed to tracheal intubation with manual or mechanical ventilation. Investigate and treat any underlying condition.

PROBLEM 2.3 Unilateral Chest Movements in the Intubated Ventilated Patient

POTENTIAL CAUSES

1. Bronchial intubation
2. Bronchial obstruction
3. Lung collapse, pneumothorax
4. Hemothorax, pleural effusion
5. Consolidation, absent lung (pneumonectomy)

ACTION

If bronchial intubation is suspected, deflate the tracheal tube cuff and slowly withdraw the tube 1 to 2 cm. Reinflate the cuff, and manually ventilate the patient while auscultating both sides of the chest. Is air entry present and equal on both sides? Be

suspicious if the tube has to be withdrawn more than 3 to 4 cm or if the tube length at the teeth is much less than the expected correct length; another underlying cause may be involved. In an adult, the average distance from the vocal cords to the carina is 12 cm. The tip of an 8.0 (adult) tracheal tube typically is 6.5 cm below the upper surface of the balloon, which must sit below the vocal cords. Therefore, if the upper surface of a cuff is only 3 cm below the vocal cords, the tip will be within 2 to 3 cm of the carina. It is easy to inadvertently intubate a bronchus or leave the tip of the tube close enough to enter the bronchus with head movement or when moving the patient. In adults with normal bronchial anatomy, the tube tip usually will pass into the right main bronchus.

PROBLEM 2.4 Sudden Airway or Ventilatory Compromise in Ventilated Patient with Orotracheal Tube

A ventilated patient with an orotracheal tube in place may suddenly develop dyspnea, hypoxemia, hypercarbia, and a seesaw respiratory pattern. The mechanical ventilator alarm will sound.

POTENTIAL CAUSES

1. Failure of oxygen or air supply to the ventilator
2. Ventilator disconnection or obstruction in ventilator circuit
3. Obstructed tracheal tube
 - Plugged by mucus or clot
 - Kink in tracheal tube
 - Biting on tube (previous biting may have narrowed the tube)
 - Obstruction of tube tip by side wall of lower airways or carina
4. Patient's fighting against ventilator
5. Respiratory fatigue (e.g., with weaning from mechanical support or new infection)
6. Pneumothorax or tension pneumothorax
7. Rapid development of large hemothorax or pleural effusion

ACTION

Disconnect the patient from the ventilator, and ventilate through the tracheal tube manually. Have the ventilator and circuit checked by another appropriate staff member. High resistance or inability to inflate the lungs suggests tube obstruction or an intrathoracic problem. The (recent) inability to pass a suction catheter down the lumen is suggestive of tube obstruction. If the patient's condition is stable or improving, a small fiberoptic bronchoscope or laryngoscope (if readily available) may be passed down the tube. An obstruction may be removed by suction catheter, or removal of the tube and use of mask ventilation (to reverse hypoxemia and hypercarbia), followed by reintubation, may be required. If no answer to the problem is found, consider whether the patient's condition could be due to a tension pneumothorax. If appropriate, use needle decompression. Otherwise, order emergency chest film and continue either manual or mechanical ventilation as appropriate.

PROBLEM 2.5 Sudden Airway or Ventilatory Compromise in Ventilated Patient with Tracheostomy

A ventilated patient with a tracheostomy may suddenly develop dyspnea, hypoxemia, hypercarbia, and a seesaw respiratory pattern. The mechanical ventilator alarm will sound.

POTENTIAL CAUSES

Causes may include all those listed for [Problem 2.4](#).

ACTION

Appropriate interventions are the same as for [Problem 2.4](#), with an appreciation of the fact that tracheostomy tubes are shorter, more curved, and more rigid than tracheal tubes. They rarely kink but may become blocked with secretions or blood.^{31,178} Suctioning the tube may resolve this. Double-skinned tracheostomy tubes may be unblocked by removing the inner tube (containing the obstruction) for washing, leaving the outer tube in place to maintain a clear airway. Such double-skinned tubes are safer for patients discharged to general wards. Tracheostomy tubes also may become obstructed when the distal opening is blocked by a mucosal flap, the side wall of the trachea, or (rarely) the carina.

KEY POINTS

- The difficult airway may be unanticipated despite expert preassessment. Airway practitioners must have plans to deal with this scenario.
- Use of the appropriate size and type of laryngoscope blade in conjunction with other adjuncts and techniques is an important element of successful tracheal intubation—particularly with the unanticipated difficult airway.
- Airway difficulty in critical care is common and may be precipitated long after intubation by acute events such as tube dislodgement or obstruction.
- Tube dislodgement in critical care is potentially avoidable and may be influenced by staffing levels, sedation policy, and other bedside factors.
- Surgical cricothyrotomy is a relatively simple procedure and may be used to establish a medium-term airway, avoiding the need for tracheostomy.
- In critical care, removal of a tracheal tube may precipitate an acute difficult airway scenario. A protocol for handling a difficult reintubation should always be in place.
- All critical care physicians should be familiar with one or more difficult airway algorithms and the practical skills they require.

Assessment of Cardiac Filling and Blood Flow

Martin Geisen | Maurizio Cecconi | Andrew Rhodes

CHAPTER OUTLINE

CARDIAC FILLING

Preload

Contractility

Afterload

Clinical Limitations of Systemic Vascular Resistance and Pulmonary Vascular Resistance

Clinical Interpretation of Indicators of Preload

HEMODYNAMIC STATUS AND BLOOD FLOW

Measurement of Cardiac Output

Assessment of Adequacy of the Circulation

GOAL-DIRECTED THERAPY

Hemodynamic Optimization of the High-Risk Surgical Patient

Early Goal-Directed Therapy of Severe Sepsis

CONCLUSIONS

The accurate assessment and manipulation of the circulation are important parts of the management of critically ill patients. The principal objective of cardiorespiratory manipulation is to ensure optimal oxygen delivery. Adequate cellular respiration, adequate delivery of substrates and pharmaceuticals, and eventual recovery of organs and tissues are possible only when this has been achieved. This chapter deals with the physiologic principles governing the cardiovascular system and discusses interpretation of hemodynamic data in a clinical context. With the increasing number of medical devices available to monitor the circulation, this chapter also outlines the principles underlying the design and function of these devices, as well as their uses and limitations (Tables 3.1 to 3.4).

CARDIAC FILLING

One of the fundamental concepts of hemodynamic optimization of the critically ill patient is the manipulation of cardiac output as a main determinant of blood flow and oxygen delivery. Cardiac output is defined as the product of stroke volume (SV) and heart rate (HR). Although options to control heart rate are limited, clinical studies investigating hemodynamic optimization protocols have been largely focused on interventions to increase stroke volume. The stroke volume of the heart is determined by the complex interaction of three components: preload, contractility, and afterload. A thorough understanding of the physiology and pathophysiologic principles that define these components is essential for the clinician to successfully control and improve cardiovascular dynamics.

Our current understanding of the relationship between preload and contractility and their effect on stroke volume is based on the experiments of Dario Maestrini, Otto Frank, and Ernest Starling. Culminating in Starling's "law of the heart," which states that the force of myocardial contraction is directly proportional to the end-diastolic myocardial fiber length (or "preload"), as determined by the ventricular end-diastolic volume (EDV).^{1,2} It is this relationship, commonly known as the Frank-Starling mechanism that matches venous return to cardiac output (Fig. 3.1).

The most common intervention used by clinicians to improve stroke volume—the administration of fluids—is aimed at increasing venous return as a main determinant of EDV. In this regard two factors are important to consider: the position of an individual heart on the Frank-Starling curve and the expected response to fluid administration, as well as giving the right amount of fluid in order to achieve a hemodynamic response. The dynamics of venous return have been extensively described by Arthur Guyton, whose theories contribute to our current understanding of the circulation and may help to optimize venous return.^{3,4}

PRELOAD

Based on Ernest Starling's observations, preload is defined as the tension developed by the stretch of the myocardial fibers: An increase in venous return leads to an increase in EDV which in turn increases myocardial sarcomere length, resulting in an increase of contractility and a rise in stroke volume and cardiac output. Conversely, a decrease in venous return will reduce EDV, resulting in a decreased stroke volume and cardiac output. This mechanism matches the mechanical activity of both ventricles under changing

Table 3.1 Primary Measured Hemodynamic Data

Parameter/Formula	Normal Range
Arterial blood pressure (BP)	
Systolic (SBP)	90-140 mm Hg
Diastolic (DBP)	60-90 mm Hg
Mean arterial pressure (MAP): [SBP + (2 × DBP)]/3	70-105 mm Hg
Right atrial pressure (RAP)	2-6 mm Hg
Right ventricular pressure (RVP)	
Systolic (RVSP)	15-25 mm Hg
Diastolic (RVDP)	0-8 mm Hg
Pulmonary artery pressure (PAP)	
Systolic (PASP)	15-25 mm Hg
Diastolic (PADP)	8-15 mm Hg
Mean pulmonary artery pressure (MPAP): [PASP + (2 × PADP)]/3	10-20 mm Hg
Pulmonary artery occlusion pressure (PAOP)	6-12 mm Hg
Left atrial pressure (LAP)	6-12 mm Hg
Cardiac output (CO): HR × SV/1000	4.0-8.0 L/min

HR, heart rate; SV, stroke volume.

Table 3.2 Derived Hemodynamic Data

Derived Parameter/Formula	Normal Range
Cardiac index (CI): CO/BSA	2.5-4.0 L/min/m ²
Stroke volume (SV): CO/HR × 1000	60-100 mL/beat
Stroke volume index (SVI): CI/HR × 1000	33-47 mL/m ² /beat
Systemic vascular resistance (SVR): 80 × (MAP – RAP)/CO	1000-1500 dyn·s/cm ⁵
Systemic vascular resistance index (SVRI): 80 × (MAP – RAP)/CI	1970-2390 dyn·s/cm ⁵ /m ²
Pulmonary vascular resistance (PVR): 80 × (MPAP – PAOP)/CO	<250 dyn·s/cm ⁵
Pulmonary vascular resistance index (PVRI): 80 × (MPAP – PAOP)/CI	255-285 dyn·s/cm ⁵ /m ²

BSA, body surface area; CO, cardiac output; HR, heart rate; MAP, mean arterial pressure; MPAP, mean pulmonary artery pressure; RAP, right atrial pressure; PAOP, pulmonary artery occlusion pressure.

Table 3.3 Hemodynamic Parameters—Adult

Parameter/Formula	Normal Range
Left ventricular stroke work (LVSW): SV × (MAP – PAOP) × 0.0136	58-104 g·m/beat
Left ventricular stroke work index (LVSWI): SVI × (AP – PAOP) × 0.0136	50-62 g·m/m ² /beat
Right ventricular stroke work (RVSW): SV × (MPAP – RAP) × 0.0136	8-16 g·m/beat
Right ventricular stroke work index (RVSWI): SVI × (MPAP – RAP) × 0.0136	5-10 g·m/m ² /beat
Coronary artery perfusion pressure (CPP): Diastolic BP – PAOP	60-80 mm Hg
Right ventricular end diastolic volume (RVEDV): SV/EF	100-160 mL
Right ventricular end systolic volume (RVESV): EDV – SV	50-100 mL
Right ventricular ejection fraction (RVEF): SV/EDV	40-60%

BP, blood pressure; CO, cardiac output; EF, ejection fraction; HR, heart rate; MAP, mean arterial pressure; MPAP, mean pulmonary artery pressure; PAOP, pulmonary artery occlusion pressure; RAP, right atrial pressure; SV, stroke volume; SVI, stroke volume index.

Table 3.4 Oxygenation Parameters—Adult

Parameter/Formula	Normal Range
Partial pressure of arterial oxygen (PaO ₂)	80-100 mm Hg
Partial pressure of arterial carbon dioxide (PaCO ₂)	35-45 mm Hg
Bicarbonate (HCO ₃ ⁻)	22-28 mEq/L
pH	7.38-7.42
Arterial oxygen saturation (SaO ₂)	95-100%
Mixed venous oxygen saturation (SvO ₂)	60-80%
Arterial oxygen content (CaO ₂): (0.0138 × Hb × SaO ₂) + (0.0031 × PaO ₂)	17-20 mL/dL
Venous oxygen content (CvO ₂): (0.0138 × Hb × SvO ₂) + (0.0031 × PvO ₂)	12-15 mL/dL
Arteriovenous oxygen content difference [C(a – v)O ₂]: CaO ₂ – CvO ₂	4-6 mL/dL
Oxygen delivery (DO ₂): CaO ₂ × CO × 10	950-1150 mL/min
Oxygen delivery index (DO ₂ I): CaO ₂ × CI × 10	500-600 mL/min/m ²
Oxygen consumption (VO ₂): C(a – v)O ₂ × CO × 10	200-250 mL/min/m ²
Oxygen consumption index (VO ₂ I): C(a – v)O ₂ × CI × 10	120-160 mL/min/m ²
Oxygen extraction ratio (O ₂ ER): [(CaO ₂ – CvO ₂)/CaO ₂] × 100	22-30%
Oxygen extraction index (O ₂ EI): [(SaO ₂ – SvO ₂)/SaO ₂] × 100	20-25%

CI, cardiac index; CO, cardiac output; Hb, hemoglobin.

Figure 3.1 Graph demonstrating the Frank-Starling principle: The effect of preload on stroke volume in three different myocardial contractility states. LVEDV, left ventricular end diastolic volume; SV, stroke volume.

physiologic conditions and functions independent of nervous supply.

Preload is determined by the following factors:

- Circulating blood volume
- Venous capacitance (i.e., sympathetic stimulation resulting in venoconstriction, mechanical compression)
- Posture: The Trendelenburg position (supine, head down) increases venous return. Clinically, a passive leg raise test may be performed to assess volume responsiveness by autotransfusion of approximately 300 mL of blood from the splanchnic and lower limb compartments to the central circulation, increasing preload.
- Intracavitary pressures: Abdominal hypertension and increased intrathoracic pressures (i.e., during positive-pressure ventilation and application of positive end-expiratory pressure [PEEP]) can oppose venous return.
- Ventricular compliance: Ventricular compliance determines the relationship between EDV and end-diastolic pressure (i.e., diastolic dysfunction or impaired relaxation as in ventricular hypertrophy).
- Heart rate: The filling time influences EDV.
- Atrial contraction: Atrial contraction contributes to EDV and may be impaired (i.e., in atrial fibrillation).

INDICATORS OF PRELOAD

In vivo measurement of sarcomere length is not possible. To assess this variable in the clinical setting, ventricular end-diastolic pressures have been traditionally used as surrogate parameters to estimate EDV. Although EDV can be assessed by echocardiography, continuous monitoring of this parameter is currently not possible. Static indices of preload include traditional parameters assessing filling pressures or volumes as well as parameters derived from recently introduced techniques based on thermodilution (see later), which have been classified as volumetric indices of preload. Recently, parameters based on the cyclic changes in intra-thoracic pressure during mechanical ventilation have been introduced as estimates of preload responsiveness under certain circumstances, although they do not measure preload per se. These dynamic indices of preload can play a role in predicting an increase of stroke volume after an increase of preload, or in other words, the “fluid responsiveness” of the ventricle.

STATIC INDICATORS OF PRELOAD

These parameters give an estimate of preload, but their ability to predict a response to fluid administration is limited. Static preload indices have been defined for both sides of the heart:

Static indices of the left side of the heart:

- Left ventricular end-diastolic volume (LVEDV)
- Left ventricular end-diastolic pressure (LVEDP)
- Left atrial pressure (LAP)
- Pulmonary artery occlusion or “wedge” pressure (PAOP or PAWP)

Static indices of the right side of the heart:

- Right ventricular end-diastolic volume (RVEDV)
- Right ventricular end-diastolic pressure (RVEDP)
- Right atrial pressure (RAP)
- Central venous pressure (CVP)

It is generally postulated that EDVs correspond to myocardial sarcomere length just prior to ventricular contraction and that end-diastolic pressures correspond with EDVs.

For the left side of the heart these relationships are as follows:

$$\text{PAOP} = \text{LAP} = \text{LVEDP} \approx \text{LVEDV}$$

For the right side of the heart these relationships are as follows:

$$\text{CVP} = \text{RAP} = \text{RVEDP} \approx \text{RVEDV}$$

It is important to note that these assumptions do not hold true in most clinical conditions and all parameters are influenced by physiologic and technologic factors. Ventricular pressures and volumes both are influenced by ventricular compliance, so there is only a poor relationship between the two, and the traditional assumption that CVP, RAP, PAOP, and LAP estimate LVEDP as an indicator of LVEDV has to be questioned. PAOP reflects left ventricular function only if the vascular system between the catheter tip and the left ventricle is free from any pathologic condition that could influence the pressures detected by the catheter.

PAOP *overestimates* LVEDP in the following conditions:

- Chronic mitral stenosis
- PEEP
- Left atrial myxoma
- Pulmonary hypertension

PAOP *underestimates* LVEDP in the following conditions:

- Poorly compliant left ventricle
- LVEDP greater than 25 mm Hg

PAOP readings are accurate only if the tip of the pulmonary artery catheter (PAC) is appropriately wedged in West lung zone 3, corresponding to the lower third of the lung where continuous blood flow can be assumed.

The PAOP does not predict preload and bears little or no relationship to the subsequent response to a volume challenge. It is important to realize, however, that pressure is one of the driving forces responsible for edema formation in the lungs. In this regard, the PAOP may function as more of a safety limit rather than as a guide to therapy.⁵⁻⁷

The CVP reflects RAP and has been traditionally used as a marker of right ventricular preload and, assuming a relationship between CVP, RVEDP, and RVEDV, of left ventricular preload. However, CVP does not accurately reflect left ventricular preload and has been shown to correlate poorly with blood volume.⁵⁻⁷ The main clinical value of measuring CVP is to provide information about the right side of the heart, as in cases of right ventricular failure or in assessing the right ventricular response to pulmonary hypertension. A low CVP in the setting of clinical signs of tissue hypoperfusion may be predictive of a benefit from fluid administration, and a rapid significant rise of CVP during a fluid challenge may indicate that the heart is not fluid responsive.⁸⁻¹²

VOLUMETRIC INDICATORS OF PRELOAD

Based on cardiac output measurements using thermodilution and incorporating indicator passage times, volumetric preload parameters have been introduced as an alternative to conventional “static” parameters and have become available with thermodilution-based monitoring techniques such as the PAC, pulse contour continuous cardiac output (PiCCO), and EV1000 systems. The continuous end-diastolic volume index (CEDVI), derived from a modified PAC is a surrogate of RVEDV. Global end-diastolic volume index (GEDVI), intrathoracic blood volume index (ITBVI), and extravascular lung water index (EVLWI) are parameters provided by devices that require transpulmonary thermodilution for the measurement of cardiac output based on pulse pressure analysis (i.e., PiCCO and EV1000 systems, see later). GEDVI represents the total intracardiac volume, and the volume of the descending aorta has been shown to be a better indicator of preload than CVP.^{13,14}

DYNAMIC INDICATORS OF PRELOAD (OR PRELOAD RESPONSIVENESS)

Based on the study of heart-lung-interactions a number of so-called dynamic preload indicators have been introduced. Although these parameters are not measures of preload per se, they play an important role in the prediction of the hemodynamic response (i.e., by an increased cardiac output) to an increase in preload (preload or “volume” responsiveness). Generally, these parameters are based on the observation that transient changes in preload occur during mechanical ventilation.^{15,16}

Stroke Volume Variation

During mechanical ventilation each positive-pressure breath induces a decrease in venous return. In conditions of decreased volume status, when the right ventricle is responsive to an increase in preload, a reduction in right ventricular outflow will occur and result in a decrease of left ventricular preload after the number of cardiac cycles it takes to pump blood through the lung (pulmonary transit time). If the left ventricle is preload responsive as well, a transient decrease in stroke volume will occur. This cyclic

variation in stroke volume (stroke volume variation, SVV) can indicate volume responsiveness if it reaches a certain degree and may describe the response to a volume challenge in relation to changes in cardiac output.¹⁷⁻²¹

Pulse Pressure Variation

Similar to SSV, a marked respiratory variation of the arterial pulse pressure (pulse pressure variation, PPV) has been found to accurately predict volume responsiveness.²²⁻²⁴

SVV, PPV, and systolic pressure variation (SPV) are automatically calculated by an array of cardiac output monitors.

Plethysmographic Variability Index

The pulse oximeter plethysmographic waveform has been shown to display respiratory variations during mechanical ventilation, which can be predictive of volume responsiveness. Calculation of the plethysmographic variability index (PVI) is performed by measuring changes of the perfusion index (PI = pulsatile infrared signal/nonpulsatile infrared signal × 100) over at least one respiratory cycle.²⁵⁻²⁷

Indices Derived by Echocardiography

Finally, respiratory variations of the inferior vena cava diameter as measured by transthoracic echocardiography (TTE) or the superior vena cava (SVC) diameter as measured by transesophageal echocardiography (TEE) have been shown to accurately predict volume responsiveness.^{28,29}

It is important to note that these variables are reliable only during controlled mechanical ventilation. Other conditions in which the use of these parameters cannot be advised are as follows:

- Cardiac arrhythmias
- Application of low tidal volumes (i.e., <8 mL/kg)
- Open chest conditions
- Right ventricular failure

CONTRACTILITY

Ventricular contractility, or inotropy, describes the strength of ventricular contraction. It is defined as the tension developed by myocardial fibers at a given preload and afterload and the velocity of the shortening of the myocardial sarcomeres. It represents the intrinsic ability of the myocardium to generate a force independent of filamental stretch or ventricular loading conditions. Contractility is influenced by the following factors:

Factors that *increase* myocardial contractility:

- Circulating catecholamines
- Drugs (inotropes, digoxin, calcium solutions)
- Metabolic state (i.e., hyperthermia)
- Sympathetic nervous system activity
- Increased heart rate

The following factors *reduce* myocardial contractility:

- Hypoxia or hypercapnia
- Metabolic state (acidosis, hypothermia, hyperkalemia, hypocalcemia)
- Drugs (e.g., β -adrenergic receptor antagonists, digoxin)

- Acute and chronic cardiomyopathies
- Parasympathetic nervous system activation

Contractility is difficult to assess in the clinical setting. The temporal rate of change of ventricular pressure (dP/dt) and its maximum value (peak dP/dt) can be derived invasively (i.e., in the cardiac catheterization laboratory) or estimated less invasively with varying accuracy by echocardiography and some cardiac output monitoring devices. This parameter has been shown to be related to ventricular function in clinical studies. Echocardiography provides additional functional assessment of ventricular wall motion and blood velocity kinetics. Parameters such as the fractional area change (FAC) and ejection fraction (EF) are no accurate measures of contractility but are related to the contractile state of the myocardium and can be used to guide therapy.

AFTERLOAD

The afterload of the heart may be considered as the ventricular wall tension required to eject the stroke volume during systole. According to the law of LaPlace, afterload relates to the stress within the wall of the ventricle developing during systolic ejection:

$$T = (P \times r)/2$$

where T = tension, P = intraventricular pressure, and r = intraventricular radius. In this equation afterload is mainly dependent on wall thickness and ventricular radius. At a given pressure, an increase in ventricular radius (i.e., dilatation of the ventricle) will increase afterload. An increase in wall thickness (i.e., ventricular hypertrophy) will reduce afterload.

Afterload for the left ventricle is increased by the following factors:

- Anatomic obstruction (e.g., aortic valve stenosis, subvalvular obstruction)
- Raised systemic vascular resistance (SVR)
- Decreased elasticity of the aorta and great vessels
- Increased ventricular volume

Afterload for the right ventricle is increased by the following factors:

- Anatomic obstruction (e.g., pulmonary valve stenosis)
- Raised pulmonary vascular resistance (PVR) (e.g., pulmonary hypertension, pulmonary embolism, hypoxia, and hypercarbia)
- Increased ventricular volume

The *Anrep effect* describes an intrinsic regulatory mechanism of the heart in response to an acute increase in afterload, which results in an initial reduction in stroke volume followed by an increase in EDV, which restores the stroke volume toward near-normal values.

INDICATORS OF AFTERLOAD

SVR and PVR are the most commonly used indicators of afterload in the clinical setting for the left and right ventricle, respectively. Vascular resistance can be described as

the mechanical property of the vascular system opposing flow of blood into a vascular bed. There are two main components of vascular resistance:

- *Flow component*—frictional opposition to blood flow through the vessels, with blood viscosity being the major determinant. Vascular resistance increases with an increase in viscosity.
- *Frequency-dependent or “reactive” component*—related to the compliance of the vessel walls and the inertia of the ejected blood. A low vascular compliance increases vascular resistance.

SVR and PVR cannot be measured directly and thus are calculated from Ohm’s law:

$$V = I \times R$$

where V = voltage, I = current, and R = resistance. Applied to cardiovascular physiology this principle looks as follows:

$$\Delta P = CO \times R$$

in which ΔP is the pressure gradient, CO (cardiac output) is “flow,” and R is the resistance.

SVR is calculated as follows:

$$SVR (\text{dyn} \cdot \text{s}/\text{cm}^5) = 80 \times (\text{MAP} - \text{RAP})/\text{CO}$$

where MAP = mean arterial pressure (mm Hg), RAP = right atrial pressure (mm Hg), and CO = cardiac output. To convert from mm Hg to dyne \times second/ cm^5 the multiplication by 80 is necessary. Normal values for SVR range from 800 to 1200 dyne \times second/ cm^5 . If standardized to body surface area, SVR is quoted as SVRI (SVR index) with normal values for SVRI ranging from 1900 to 2400 dyne \times second/ cm^5/m^2 .

The following factors affect SVR:

- *Vessel diameter*: According to the law of Hagen-Poiseuille resistance is inversely related to the fourth power of the radius. This means that a decrease in vessel diameter during vasoconstriction will result in a significant increase in SVR. Vasodilation decreases SVR.
- *Compliance* of the systemic circulation
- *Blood viscosity and hematocrit*

In the same way as SVR, PVR may be calculated using the pressure differential across the pulmonary vasculature, between the mean pulmonary artery pressure (MPAP) and PAOP:

$$PVR (\text{dyne} \times \text{second}/\text{cm}^5) = 80 \times (\text{MPAP} - \text{PAOP})/\text{CO}$$

Values for PVR are normally below 250 dyne \times second/ cm^5 . Again, PVR is often quoted as the PVR index or PVRI with a normal range between 255 to 285 dyne \times second/ cm^5/m^2 .

The following factors affect PVR:

- *Vessel diameter*: Pulmonary vasoconstriction increases PVR (i.e., during hypoxia), and vasodilation reduces PVR.
- *Positive-pressure ventilation* increases PVR.
- *Established pulmonary hypertension* increases PVR.
- *Compliance* of the pulmonary circulation affects PVR.
- *Blood viscosity and hematocrit* affect PVR.

Figure 3.2 Relationship among pressure, flow, and resistance. The critical opening pressure reflects the pressure in the vasculature at zero flow. The important point to recognize is that this is not at the origin of the graph. This means that even when the flow is zero, a baseline pressure exists. Estimating systemic vascular resistance by calculating the gradient of pressure and flow for any given point will therefore be inaccurate, because the “line” is actually nonlinear and does not go through the zero origin.

CLINICAL LIMITATIONS OF SYSTEMIC VASCULAR RESISTANCE AND PULMONARY VASCULAR RESISTANCE

Although the concept of vascular resistance permits an intuitive understanding of the circulation, a number of limitations make it unreasonable to use SVR and PVR to guide therapy. First, because SVR and PVR are derived variables, errors inherent in the measurement of their components (i.e., filling pressures) are multiplied, making the derived number less accurate. Further, these calculations assume a linear relation between pressure and flow, which does not exist in vivo (Fig. 3.2). It is therefore wise to use these parameters with caution and consider their limitations in clinical practice.

CLINICAL INTERPRETATION OF INDICATORS OF PRELOAD

It has already been stressed that accurate assessment of the preload status of the heart is important because it may allow for the application of interventions resulting in an improvement of cardiovascular dynamics. However, without knowing whether the heart will actually respond to an increase of a certain status of volume or preload, this information is only of limited value. This concept—the individual response of cardiac output to a volume challenge—has become known as *volume responsiveness*.³⁰ Intravascular volume expansion is often the initial intervention in patients with circulatory failure. However, only approximately 50% of patients given a fluid challenge will respond by increasing cardiac output. The ability to distinguish fluid-responsive patients from nonresponders is important to avoid inappropriate and potentially harmful fluid challenges in situations in which other interventions (i.e., inotropes or vasopressors) should be preferentially used. Consequences of inappropriate fluid therapy include pulmonary edema, deterioration in gas exchange, and cardiac failure.

There are currently a number of parameters available with different monitoring modalities that can be used as estimates of preload and may predict volume responsiveness under defined conditions.

STATIC INDICATORS OF PRELOAD

Conventional static markers of cardiac preload, such as CVP and PAOP, are poor predictors of fluid responsiveness. CVP and PAOP reflect intracavitary pressures that frequently show poor correlation with transmural pressures, which are actually related to EDV through chamber compliance. Therefore, EDV is overestimated (i.e., under the application of PEEP) or underestimated (i.e., in concentric left ventricular hypertrophy) in many clinical situations. Furthermore, static parameters do not determine the position of the heart on the “individual” Frank-Starling curve as contractile function is not taken into the account. A patient may fail to respond to a fluid challenge because of ventricular dysfunction or poor ventricular compliance (see Fig. 3.1). It is important to realize, however, that pressure is one of the driving forces responsible for edema formation in the lungs. So although the PAOP is considered to have limited utility for predicting and guiding fluid challenges, it does have a role to play in determining how much volume should be administered to patients and may be regarded as more of a safety limit, rather than as a guide to therapy.^{5,6}

VOLUMETRIC INDICATORS OF PRELOAD

The continuous end-diastolic volume (CEDV), global end-diastolic volume (GEDV), and intrathoracic blood volume (ITBV) are computed by some monitoring systems. Although CEDV and GEDV seem to be better indicators of preload than static parameters, they are still poor predictors of a response to a fluid challenge in most situations. Extravascular lung water (EVLW) has been shown to help in the identification of noncardiogenic pulmonary edema and has the potential to increase the safety of fluid therapy in patients with structural lung disease or acute lung injury (ALI) and acute respiratory distress syndrome (ARDS).^{31,32}

DYNAMIC INDICATORS OF PRELOAD

A number of dynamic parameters have been described that allow the clinician at the bedside to predict with some accuracy which patients will or will not respond to a fluid challenge. These parameters include the SVV, PPV, SPV, and the PVI and changes of vena cava diameters as derived by echocardiography. Generally, an SPV, PPV, SVV, or PVI variation greater than approximately 10% suggests that the patient will be volume responsive (Fig. 3.3). As stressed earlier in this chapter, these parameters require controlled mechanical ventilation and a tidal volume of at least 8 mL/kg of body weight to be maintained in order to remain reliable. Further, the presence of arrhythmias and severe tricuspid regurgitation precludes the safe use of these variables.¹⁶

The Passive Leg-Raising Test

Patients who are critically ill seldom fulfill criteria to allow for dynamic preload indices to be accurate predictors of volume responsiveness. The passive leg-raising test has been suggested to overcome these limitations: Traditionally performed by lifting the legs up at a 45-degree angle in a supine position, approximately 150 mL of blood can be recruited

Figure 3.3 Stroke volume variation (SVV). The arterial pressure trace can be used to generate stroke volume (SV) on a beat-to-beat basis. The variation in SV—SVV—with mechanical ventilation is a useful marker for identifying patients who are likely to respond to an increase in intravascular volume. This tracing demonstrates the fluctuations in SV in a patient with an increased SVV.

to increase venous return in order to predict a response of cardiac output to a noninvasive, endogenous fluid challenge. However, by starting the passive leg raising from a 45-degree semirecumbent position, a substantial increase of mobilized venous blood can be achieved by adding venous blood from the splanchnic compartment to that from the lower extremities, increasing the sensitivity of the maneuver for the prediction of fluid responsiveness. It is important to note that when performing the passive leg raising, the monitoring modality used must be able to track changes in cardiac output within a time frame of approximately 60 to 90 seconds.³³⁻³⁵

The Diagnostic Fluid Challenge

In the care of critically ill patients situations do exist in which the preceding parameters are not reliable and a passive leg-raising test may be contraindicated owing to technical constraints or based on the patient's underlying illness, such as in brain injury with elevated intracranial pressure. In this scenario the clinician may rely on the administration of fluids as a diagnostic intervention to indicate a potential benefit from further fluid therapy by assessing the response of various hemodynamic parameters, with stroke volume being the parameter most widely used in studies investigating fluid responsiveness, with an increase of 10% to 20% indicating a positive response. Although the optimal volume to function as a fluid challenge has yet to be determined, it can be recommended in this situation to use the CVP as an indicator of a sufficient challenge of the right ventricle to ensure that an adequate preload has been achieved.^{36,37}

It is important to recognize, however, that identification of a patient who is fluid responsive is not the same as saying that the patient should be given fluid without an appreciation of the clinical context. Most healthy patients will be volume responsive; however, few will benefit from volume challenges. In critically ill patients, other clinical factors need to be taken into account. Does the patient actually need a higher cardiac output? Or is cardiac output adequate, so that further increase may actually cause harm?

HEMODYNAMIC STATUS AND BLOOD FLOW

Cardiac output (or blood flow) is an important variable to be considered in a critically ill patient. Although arterial

pressure has been used as the target for therapy, this focus is perhaps related more to convenience in measurement than to a sound physiologic rationale. When patients become critically ill, it is extremely difficult to predict cardiac output from routine clinical assessment, so sensible and logical use of vasoactive therapy requires monitoring of both pressure and flow. Arterial blood pressure often is mistakenly used as a surrogate marker for blood flow; however, no direct relationship between pressure and flow exists. Moreover, clinical estimation of cardiac output can be difficult and inaccurate, although clinical assessment must not be ignored. Often these signs constitute the only tool that a clinician may have to estimate a patient's hemodynamic status before admission to a critical care unit. At this stage the response of clinical assessment to simple therapeutic maneuvers can give important information. If, however, the patient fails to respond in a suitable fashion, monitoring of these variables becomes necessary in order to direct therapy.

Cardiac output is the volume of blood ejected by the left ventricle per minute. It is the product of heart rate and stroke volume. It should be borne in mind that excessive heart rates will reduce diastolic ventricular filling time, with a negative impact on stroke volume. Heart rhythm also is essential in determining cardiac output, and in general any rhythm other than sinus rhythm will result in a reduction in stroke volume. For example, the loss of atrial contribution to diastolic ventricular filling in atrial fibrillation results in a subsequent reduction in stroke volume and hence cardiac output.

Cardiac output should not be considered in isolation from other relevant variables. The concept of oxygen delivery describes the relationship between cardiac output and arterial oxygen content:

$$\text{Oxygen delivery} = \text{Arterial O}_2 \text{ content} \times \text{Cardiac output}$$

This variable (oxygen delivery) has been used in many studies, especially in the high-risk surgical population, as a target for resuscitation.

MEASUREMENT OF CARDIAC OUTPUT

The ideal method of measuring cardiac output would be noninvasive, accurate, continuous, safe, easy to use, and operator independent; would provide rapid data acquisition; and would be cost effective. None of the cardiac output monitoring devices currently available possesses all of these properties. Conventional thermodilution remains the clinical gold standard for accuracy in cardiac output measurement; however, newer, less invasive monitoring methods that provide continuous cardiac output data are establishing a role in patients' hemodynamic management.³⁸

THE FICK PRINCIPLE

Fick described the following relationship in the nineteenth century: $Q = M / (A - V)$. That is, the uptake or release of a substance (M) by an organ is the product of the blood flow (Q) through that organ and the arteriovenous concentration difference (A - V) of the substance in question.

Applying the Fick principle to cardiac output measurement of the pulmonary blood flow over 1 minute may be achieved by measuring the arteriovenous oxygen content

difference across the lungs and the rate of oxygen uptake. Oxygen uptake may be determined using spirometry by measuring the expired gas volume over a known time and calculating the difference in oxygen concentration between the expired gas and that of inspired gas. Accurate collection of the gas is difficult, unless the patient has an endotracheal tube, because of the leaks that occur around a facemask or mouthpiece. Analysis of the gas is straightforward if the inspired gas is air, but if it is oxygen-enriched air, two possible problems need to be taken into consideration: (1) the addition of oxygen may fluctuate, producing an error due to the nonconstancy of the inspired oxygen concentration, and (2) measurement of small changes in oxygen concentration at the top end of the scale is difficult. Blood oxygen content is measured via blood gas analysis. In the absence of intrapulmonary or intracardiac shunts, the pulmonary blood flow is equal to the systemic blood flow and thus cardiac output.

The technique just described based on the Fick principle may thus be used as an accurate and reliable static measure of cardiac output, but it remains a time-consuming and largely laboratory-based tool. Several variants of the basic method have been devised, but usually their accuracy is less reliable.

THERMODILUTION

As mentioned earlier, thermodilution from the PAC is considered to be the gold standard of cardiac output measurement for accuracy and acceptability in the clinical setting. Newer methods are routinely validated against the PAC thermodilution technique. A bolus of 5 to 10 mL of cold 0.9% NaCl or 5% dextrose is injected through the proximal port of a PAC into the right atrium. Temperature changes are measured by a distal thermistor in the pulmonary artery. A plot of temperature change against time gives a thermodilution curve from which cardiac output can be calculated from the Stewart-Hamilton equation (Fig. 3.4). Application of this equation assumes three major conditions: complete mixing of blood and indicator, no loss of indicator between place of injection and place of detection, and constant blood flow. For accurate results with this technique, it is important to ensure adherence to these conditions.

The degree of change in the temperature is inversely proportional to the cardiac output.

- Increased blood flow (and cardiac output) = minimal temperature change
- Decreased blood flow (and cardiac output) = pronounced temperature change

Modern PACs are able to provide a continuous reading of cardiac output. They contain an electrical heating coil that sits in the right atrium, which heats up the blood in a semirandom binary fashion. The pulsed heating bursts can be detected by the thermistor in the pulmonary artery, which after autocorrelation with the inputting signal can provide continuous cardiac output. It has to be noted, however, that this technique has a latency of 7 to 10 minutes.

DYE/INDICATOR DILUTION

A number of techniques are available to measure cardiac output with the use of either a dye (indocyanine green) or

Figure 3.4 Thermodilution curves: A plot of temperature change versus time following a bolus of cold injectate. Cardiac output is inversely proportional to the area under the thermodilution curve. With a large cardiac output, the bolus is pumped rapidly past the thermistor, so the area is small.

an indicator (lithium). The concept is exactly the same as that for thermodilution: injection of a substance into the right side of the heart and detection of the same substance distally, either in the pulmonary artery or in the aorta. A curve is generated, which is replotted semilogarithmically to correct for recirculation of the dye. Cardiac output is calculated from the injected dose, the area under the curve (AUC), and the duration of effect (short duration indicates high cardiac output) from the Stewart-Hamilton equation:

$$\dot{Q} = \frac{V(T_B - T_1)K_1K_2}{T_B(t)dt}$$

\dot{Q} = cardiac output

V = volume of injectate

T_B = blood temperature

T_1 = injectate temperature

K_1K_2 = computer constants

$T_B(t)dt$ = change in blood temperature over time

ARTERIAL PULSE PRESSURE ANALYSIS

Arterial pulse pressure analysis is a technique of measuring and monitoring stroke volume on a beat-to-beat basis from the arterial pulse pressure waveform. This technique has several advantages over technologies such as the PAC,

including its less invasive nature, as arterial access is available in most patients. Changes in both stroke volume and cardiac output are then shown on an almost continuous basis. A fair amount of less invasive cardiac output monitoring devices based on pulse pressure analysis are now commercially available and have resulted in a decreased use of the pulmonary catheter in most institutions (Table 3.5).

The fluctuations of blood pressure around its mean value occur as a specific volume of blood—the stroke volume—is forced into the aorta by each cardiac contraction. The

magnitude of this pressure change, the pulse pressure, is a function of the magnitude of the stroke volume. On a beat-to-beat basis, the only factor that determines changes in pulse pressure is change in stroke volume, owing to the relatively slow nature of reactive vascular changes. In order to translate the pressure waveform into an accurate stroke volume, however, an estimate of the arterial compliance and resistance must be made. The greater the compliance, the less will be the vascular resistance to the pulsatile increase in the arterial pressure, and the less will be the pressure

Table 3.5 Less Invasive Hemodynamic Monitoring Devices

required to distend the vessel to accommodate a given stroke volume.

The need to incorporate arterial compliance and resistance into the measurement system has hindered this technology for many years. The origins of the pulse contour method for estimation of beat-to-beat stroke volume are based on the Windkessel model described by Otto Frank in 1899. Only recently have methods been described that can compensate or correct for these compliance or resistance changes to provide an accurate determination of stroke volume. Different technologies address this by different methods. Both lithium dilution and thermodilution techniques have been validated to calibrate pulse pressure tracking systems. Other devices are being marketed with the ability to self-calibrate after identifying vascular compliance and resistance directly from the pressure waveform.³⁹

PROPRIETARY SYSTEMS REQUIRING CALIBRATION

PiCCO System

The PiCCO system⁴⁰ (Pulsion Medical Systems, Munich, Germany) utilizes a pulse contour method of tracking arterial pressure to derive changes in stroke volume. This system consists of a thermistor-tipped catheter, which is placed in the femoral or brachial artery. The device identifies the systolic area by recognizing the dicrotic notch on the arterial waveform. The systolic area is divided by the aortic impedance to calculate stroke volume. Transpulmonary thermodilution, requiring a central venous line, is used to calibrate the system in order to account for individual aortic compliance. In addition to tracking cardiac output and stroke volume, this technology also can provide dynamic indicators of volume responsiveness (SVV, SPV, and PPV), as well as a number of volumetric markers of preload (GEDV, ITBV, and EVLW). This system has been shown to be interchangeable with the pulmonary catheter in terms of the accuracy of measuring cardiac output and has been validated in a broad spectrum of clinical settings.⁴⁰

LiDCOplus System

The LiDCOplus⁴¹⁻⁴⁴ (LiDCO, Cambridge, UK) tracks the power of the arterial waveform, rather than the contour, in order to track changes in stroke volume. A theoretical advantage is that the effect of reflected waves is reduced because the device does not need to identify specific parts of the arterial waveform. Because the morphologic pattern is not assessed, this technology also decreases (but does not negate) the effects of damping on the pressure system. This system can be calibrated by any independent form of cardiac output monitoring device but is sold with the proprietary lithium dilution cardiac output modality. The LiDCOplus technology also tracks the dynamic parameters of preload: SVV, SPV, and PPV.

EV1000 System

The EV1000 system has been recently introduced as a monitoring device based on pulse pressure analysis. Its components include a proprietary thermistor-tipped femoral arterial catheter and a separate sensor connected to the EV1000 monitor. Calibration by transpulmonary thermodilution is required and the system offers additional

hemodynamic variables (GEDV, EVLW, SVV). Initial evaluation studies have shown a good agreement with the PiCCO system in the measurement of cardiac output and volumetric indices.^{45,46}

Uncalibrated Systems

PulsioFlex System. This system (Pulsion Medical Systems, Munich, Germany), based on the PiCCO pulse contour algorithm, uses a proprietary transducer (ProAQT) integrated into the PulsioFlex system and does not require calibration. The device has recently been introduced by Pulsion Medical Systems, and initial clinical validation studies have shown good agreement with cardiac output measurements using transpulmonary thermodilution.⁴⁷

LiDCOrapid System. This uncalibrated device uses the same algorithm as the LiDCOplus system, which has been well validated. Nomograms are used for the estimation of cardiac output instead of indicator dilution.

Flotrac. The Flotrac system (Edwards Lifesciences, Irvine, CA) consists of a proprietary transducer and a separate monitor (Vigileo). The technology assesses the variance of the arterial waveform in comparison with specific demographic characteristics of the patient to identify changes in stroke volume and analyzes statistical properties of the arterial pressure waveform to account for individual vascular resistance and compliance. Recent software updates have considerably improved the response time to changes in vascular dynamics (approx. 20 seconds), although concerns remain regarding the accuracy of cardiac output measurements in acute hemodynamic changes. Nonetheless, the Flotrac/Vigileo system has been integrated into protocols of hemodynamic optimization showing an improvement in clinical outcomes.⁴⁸⁻⁵¹

Nexfin. The Nexfin system has been introduced recently as a totally noninvasive monitor of cardiac output. This system operates by applying a stepwise approach: An arterial pressure signal generated by combining photoelectric plethysmography with an intermittently inflated pressure cuff to maintain a constant arterial diameter. This finger arterial pressure signal is converted to a brachial arterial pressure waveform, which is used to calculate cardiac output. The current algorithm uses individualized components of a three-element Windkessel model, with age, gender, height, and weight as input parameters, incorporating the nonlinear effect of mean pressure and the influence of individual characteristics on aortic mechanical properties. Clinical studies have shown adequate correlation with cardiac output derived by thermodilution. The device offers the possibility of monitoring cardiac output at a very early clinical stage and may be instrumental in early treatment initiation.⁵²

Masimo System. Although this is not a pulse pressure analysis-based monitor by definition, the Masimo system has the potential for use as an uncalibrated system for hemodynamic optimization. This device provides automated measurement of the PVI from a disposable finger sensor by measuring changes in perfusion index ($PI = \text{pulsatile infrared signal} / \text{nonpulsatile infrared signal} \times 100$)

over a time interval including at least one complete respiratory cycle.²⁵⁻²⁷

TRANSESOPHAGEAL DOPPLER⁵³⁻⁵⁶

The esophageal Doppler cardiac output monitor, described in the early 1970s, provides a safe and minimally invasive means of continuously monitoring the circulation. In comparison to suprasternal probes, esophageal probes have the advantage of less positional variety due to the smooth muscle tone of the esophagus and less signal interference from bone, soft tissue, and lung due to the close proximity of the aorta to the esophagus. The esophageal Doppler monitor measures blood flow velocity in the descending thoracic aorta using a flexible ultrasound probe. When these data are combined with the aortic cross-sectional area, other hemodynamic variables including stroke volume and cardiac output can be calculated. With the currently marketed device (CardioQ, Deltex, Chichester, UK) aortic cross-sectional area is assumed, providing minimally invasive, continuous cardiac output assessment. Abrupt changes in cardiac output are much better followed with Doppler systems than with the PAC-based continuous cardiac output systems.

Despite several potential sources of error, good correlation has been observed between measures of cardiac output made simultaneously with the esophageal Doppler monitor and with conventional thermodilution. Esophageal Doppler ultrasonography has been used for intravascular volume optimization both in the perioperative period and in the critical care setting.^{29,32-35} One of the main advantages of the technique is the capability of rapid data acquisition after esophageal probe insertion.

Identification of the descending aortic waveform is essential for the correct use of the esophageal Doppler cardiac output monitor. Waveforms from other structures, such as the pulmonary artery, azygos vein, or celiac axis, may be encountered, leading to misinterpretation. After the characteristic descending aortic waveform is acquired, the signal is optimized before data acquisition by movement of the probe a centimeter up or down until the waveform indicates the best possible velocity and color intensities, followed by rotation of the probe to optimize the signal further if possible. The “peak velocity” display is used as a reference to the highest identified wave.

Esophageal Doppler waveform analysis has been increasingly evaluated as a method for determining optimal cardiac preload. The key preload parameter of interest is the flow time (FT)—the time required from the start of the waveform upstroke to return to baseline. FT represents the duration of left ventricular systole and makes up one third of the cardiac cycle (cycle time). Because the FT is heart rate dependent, it typically is corrected (FTc) to a rate of 60 beats per minute to compensate for the change in duration of systole. The FTc reflects the afterload status of the circulation. Decreased levels commonly are seen in hypovolemic patients, but caution in interpretation is advised because this pattern also can be seen with profound vasoconstriction. A more sensible use of this device is in following the effects of a fluid challenge. Because stroke volume can be determined on a beat-to-beat basis, it is easy to see the effects on the circulation of a small fluid bolus. Diagrammatic

Interpretation of the Transesophageal Doppler Waveforms

Figure 3.5 Diagrammatic representation of characteristic Doppler waveform patterns. The characteristic flow “triangles” generated in an esophageal Doppler study can be used to monitor cardiac output and stroke volume. The width of the base of the triangle (flow time) when corrected for heart rate provides an estimate of afterload. This diagram demonstrates the changes that are seen after a volume challenge in a variety of clinical conditions.

representations of characteristic Doppler waveform patterns are shown in [Figure 3.5](#).

ECHOCARDIOGRAPHY^{57,58}

TTE and TEE both are evolving tools in the critical care setting, and particularly TEE has become a standard of care for intraoperative monitoring in patients undergoing cardiac valvular replacement or repair. TEE has been used for a number of years for acute hemodynamic monitoring and diagnostic purposes in the cardiothoracic critical care setting and its use in the general critical care setting is now becoming commonplace.

Echocardiography provides a dynamic assessment of cardiac function, allowing visualization of cardiac chamber dimensions, functional assessments such as estimation of ventricular ejection fractions, detection of regional and global wall motion abnormalities, detection of valvular abnormalities, and exclusion of pericardial effusion. It also can be used to derive cardiac output from measurement of blood flow velocity by recording the Doppler shift of ultrasound signals reflected from the red blood cells. The time-velocity integral, which is the integral of instantaneous blood flow velocities during one cardiac cycle, is obtained

for the blood flow in the left ventricular outflow tract (other sites can be used). This is multiplied by the cross-sectional area and the heart rate to give cardiac output. The results for cardiac output measured by this device in skilled hands are comparable to those obtained with use of the PAC.

The main disadvantages of the method are that a skilled operator is needed, the probe is large and therefore heavy sedation or anesthesia is needed, the equipment is very expensive, and an expert user is needed to adjust the probe to give continuous cardiac output readings. Nonetheless, echocardiography has an important and established clinical role. The modality is covered in detail in Chapter 8.

BIOIMPEDANCE AND BIOREACTANCE

Transthoracic bioimpedance is a technique initially developed as a noninvasive method of studying cardiovascular function during space flight. The underlying principle is the occurrence of changes in electrical impedance of the thoracic cavity with ejection of blood during systole.³⁷ In this model, the thorax is assumed to be a cylinder having electrical length between neck and xiphoid and has a basic impedance. A constant small current is passed between two outer electrodes attached to the skin (BioZ system) or an endotracheal tube (ECOM system), voltage change is sensed by two inner electrodes, and impedance is derived according to the equations described by Sramek and Bernstein.⁵⁹ Impedance is recognized to change with the cardiac cycle (related to changes in blood volume). The rate of change of impedance is a reflection of cardiac output. It is thought to be useful in estimating trends in cardiac output but not for absolute measurements. Contraction of the heart produces a cyclic change in transthoracic impedance of approximately 0.5%, unfortunately giving a rather low signal-to-noise ratio. Stroke volume and cardiac output can be measured continuously and at fixed intervals using this technique. Studies suggest that transthoracic bioimpedance is accurate in healthy volunteers, but its reliability decreases in critically ill patients, including those with sepsis or increased lung water, and in persons with pacemakers. Clinical evaluation studies have so far shown conflicting results and the technique has not gained wide clinical acceptance to date.⁶⁰⁻⁶²

BIOREACTANCE

As opposed to bioimpedance, this technique is based on the delivery of an oscillating electrical current and its modification by changes in stroke volume. The currently available NICOM system (Cheetah Medical, Inc., Vancouver, WA, USA) provides estimation of cardiac output by analyzing the variations in the frequency spectra of the electrical oscillations. Initial clinical validation studies have shown promising results.^{63,64}

APPLICATION OF THE FICK PRINCIPLE

The NICO (Novamatrix) system is a noninvasive device that applies Fick's principle on CO₂ and relies solely on airway gas measurement. The method actually calculates effective lung perfusion—that part of the pulmonary capillary blood flow that has passed through the ventilated parts of the lung. The effects of unrecognized ventilation-perfusion inequality in patients may explain why the results with this method show a lack of agreement between thermodilution and CO₂-rebreathing cardiac output.⁶⁵⁻⁶⁸

ASSESSMENT OF ADEQUACY OF THE CIRCULATION

Resuscitation of critically ill patients is a complex process. The rationale for most resuscitation maneuvers is that the delivery of oxygen to the tissues is inadequate, resulting in tissue hypoxia. Resuscitation is therefore aimed at increasing the oxygen delivery to a level at which enough oxygen is brought to the tissues to ensure efficient metabolism, so that normal cellular processes can occur. Part of this process entails measuring cardiac output and then increasing this variable to an “adequate” level. Unfortunately, this strategy is complicated as a result of the fact that all patients' cardiac output requirements differ—no “normal” level of flow can be specified for any patient in any given situation. In order to assess adequacy of perfusion, therefore, a number of surrogate markers need to be assessed that give an estimate of the underlying metabolic status. The cardiac output then needs to be assessed in combination with these surrogate markers of metabolism in order to ensure that resuscitation is improving the clinical situation.

CLINICAL ASSESSMENT

The first step in the hemodynamic assessment must be a thorough clinical assessment. Pulse rate and quality, respiratory rate, skin temperature, capillary refill time, core-peripheral temperature gradient, level of consciousness, and urine output are strongly related to cardiovascular dynamics, and a change in these clinical parameters may indicate deterioration as well as a positive response to a hemodynamic intervention. Skin mottling, pallor, and diaphoresis are alarming signs that need immediate and appropriate intervention. Recent studies have shown a strong relationship between clinical and microcirculatory parameters and underline their importance in hemodynamic assessment.⁶⁹⁻⁷¹

Mixed Venous Oxygenation⁷²⁻⁷⁵

SvO₂ is the oxygen saturation of mixed venous blood in the pulmonary artery. It reflects the overall venous saturation after the blood has been fully mixed in the right side of the heart. SvO₂ is related to the balance between oxygen delivery (Do₂I) and the ability to extract oxygen, or the oxygen extraction ratio (O₂ER). Under normal circumstances, oxygen consumption is independent of supply until oxygen delivery falls below the anaerobic threshold. The normal O₂ER is approximately 25%, giving an SvO₂ of 75%. In the face of a reduction in oxygen delivery, the tissues maintain oxygen consumption by increasing oxygen extraction, so SvO₂ decreases. However, SvO₂ does not necessarily vary with cardiac output. Not all patients can increase their O₂ER if Do₂I falls. Clinically, the response of SvO₂ to an increase in cardiac output or oxygen delivery can aid hemodynamic manipulation. SvO₂ can be measured by sampling blood from the distal lumen of a PAC and then measuring oxyhemoglobin saturation by means of co-oximetry, or by using an oximetric PAC that is able to continuously display SvO₂. A flow diagram of a published protocol using PAC-derived parameters is shown in Figure 3.6.

It has been suggested that SvO₂ should be monitored and the key variables manipulated to keep it within the normal range (65% to 75%). In practice, this means ensuring that

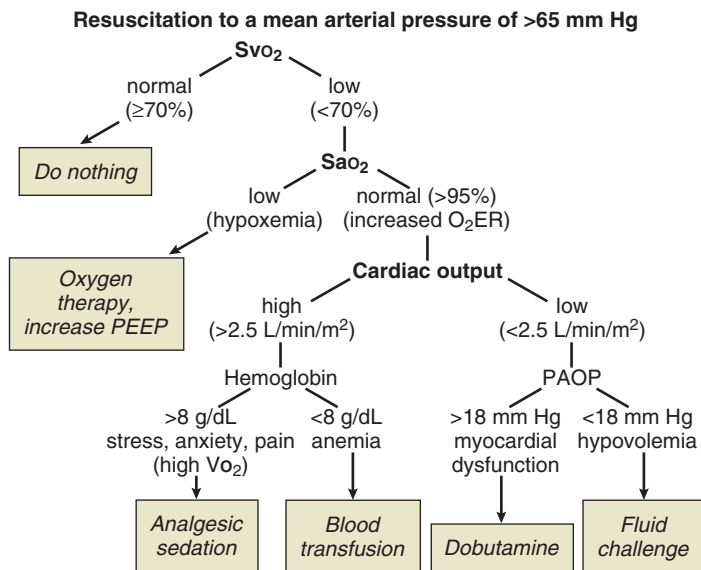

Figure 3.6 Flow chart for Pinsky-Vincent protocol. A diagnostic and treatment algorithm for the use of pulmonary artery catheter-derived variables. O₂ER, oxygen extraction ratio; PAOP, pulmonary artery occlusion pressure; PEEP, positive end-expiratory pressure; SaO₂, arterial oxygen saturation; Vo₂, oxygen consumption. (Adapted from Pinsky MR, Vincent JL: Let us use the PAC correctly and only when we need it. *Crit Care Med* 2005;33:1119-1122.)

the hemoglobin concentration and arterial oxygen saturation are normal and then either increasing cardiac output or decreasing oxygen utilization (such as by sedation or cooling). Thus, \bar{SvO}_2 monitoring provides a means of assessing the adequacy of cardiac output for a given patient. This strategy has been used with success in post-cardiac surgery patients and has been suggested for use in critically ill patients.

Central Venous Oxygen Saturation

In patients without PACs in place, central venous oxygen saturation ($ScvO_2$) may be measured by sampling from the distal lumen of a central venous line in the SVC. This variable bears some relationship to the mixed venous oxygen saturation, although because the venous blood is not totally mixed in the SVC, the relationship should be considered as representing a guide rather than reflecting reality. In practice, the central venous oxygen saturation should be used as a screening tool, rather than as an accurate marker of adequacy. If the level is very low, then the inference can be made that the circulation is inadequate; however, near-normal levels do not preclude underlying problems. The use of this variable in this fashion has proved successful in reducing mortality rates for early severe sepsis and is recommended as a target for therapy by the Surviving Sepsis Campaign.⁷⁴⁻⁷⁶

Blood Lactate

Blood lactate levels represent the balance between lactate production and lactate metabolism. The liver is responsible for the major part of lactate metabolism. Inadequate oxygen delivery and tissue hypoxia, irrespective of the underlying cause, results in increased lactate generation. In critically ill patients, high blood lactate levels develop from a

combination of inadequate oxygen delivery secondary to poor perfusion (in terms of both perfusion pressure and flow), impaired cellular oxygen utilization from mitochondrial damage, and reduced hepatic clearance of lactate. A resolving lactic acidosis along with clinical signs of improved perfusion is an important indicator of improving perfusion after resuscitation. Lactate levels and lactate clearance have been shown to predict mortality risk and morbidity, and studies investigating protocols aimed at decreasing lactate levels have shown the potential role of lactate as a treatment goal.⁷⁷⁻⁸⁰

Venous-to-Arterial CO₂ Difference (PCO₂ Gap)

Oxygen-derived parameters, namely \bar{SvO}_2 and $ScvO_2$, may falsely indicate adequate tissue perfusion in the presence of anaerobic metabolism due to microcirculatory compromise. In this situation, a decrease in oxygen consumption (Vo_2) may occur, either because of impaired oxygen delivery or reduced oxygen demand resulting in normal levels of \bar{SvO}_2 or $ScvO_2$. In hypoxic conditions due to impaired tissue perfusion a rise in the partial pressure of CO₂ (PCO₂) is usually seen, widening the gap between arterial and venous PCO₂. Recent clinical studies have suggested that the venous-to-arterial CO₂ difference using a central venous and an arterial blood sample ($P(cv-a)CO_2$ or PCO₂ gap) may be used as a complementary tool to unmask inadequate tissue perfusion in patients who are apparently resuscitated to target goals, namely, an $ScvO_2$ of 70%. Further prospective clinical studies will show if this parameter has the potential to function as a treatment goal in the resuscitation of critically ill patients with hemodynamic compromise.⁸¹⁻⁸³

GOAL-DIRECTED THERAPY

The concept of goal-directed therapy refers to the protocolized assessment and manipulation of hemodynamic variables in the resuscitation of critically ill patients. This approach became fashionable in the late 1980s and early 1990s, with a resurgence of interest in the early 2000s. Initially these protocols were relatively simple and consisted of measures to increase oxygen delivery and consumption to predefined targets. It was soon recognized that the same targets could not be used for every single group of patients undergoing different conditions and procedures, so protocols have now been refined for different patient populations.

HEMODYNAMIC OPTIMIZATION OF THE HIGH-RISK SURGICAL PATIENT

Many different protocols have been used for the management of the high-risk surgical patient.⁸⁴⁻⁹² Initially all such protocols targeted an oxygen delivery index of 600 mL/minute/m² with the use of fluids and positive inotropic agents. Measurement of cardiac output was performed through a PAC. Currently, many different protocols have been devised, some targeting oxygen delivery, some the mixed venous oxygen saturation, and some ensuring adequate volume loading by targeting a maximal stroke volume. The newer protocols reflect the more modern technologies, so they typically involve less invasive strategies and

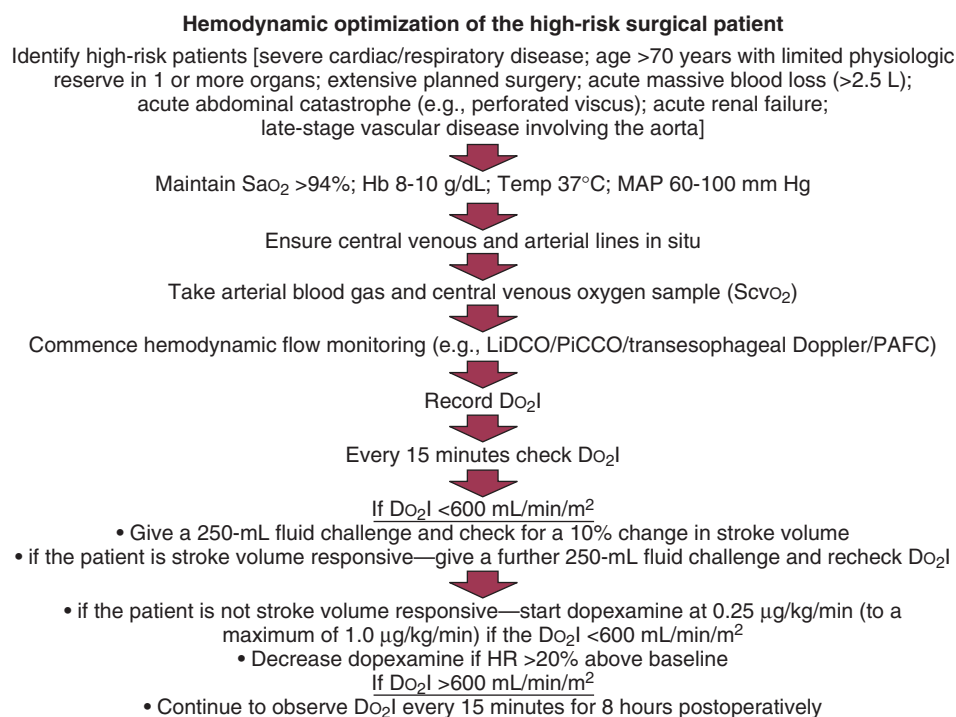

Figure 3.7 Pearse protocol for management of the high-risk surgical patient. techniques. Data suggesting one protocol over another are essentially lacking, so it is best to choose appropriate monitoring technologies and therapeutic end points in accordance with the particular characteristics of the patient group being treated and depending on availability of appropriate devices and trained practitioners. Two protocols for optimization are shown in Figures 3.6 and 3.7.

EARLY GOAL-DIRECTED THERAPY OF SEVERE SEPSIS

Resuscitation of patients with severe sepsis and septic shock has been studied with an early goal-directed approach⁷⁴ (Fig. 3.8). In this approach, cardiac output has not actually been measured; however, a number of surrogate markers of adequacy of the circulation have been targeted. Volume loading is instigated early in this protocol and then targeted against markers of lactate metabolism and central venous oxygen saturation. If these markers fail to fall, then oxygen utilization is decreased by sedation and mechanical ventilation, and oxygen delivery is increased with the use of red blood cell transfusion and a positive inotrope. It should be noticed that although different parameters are being used, this strategy is very similar in principle to that used in the high-risk surgical group of patients.

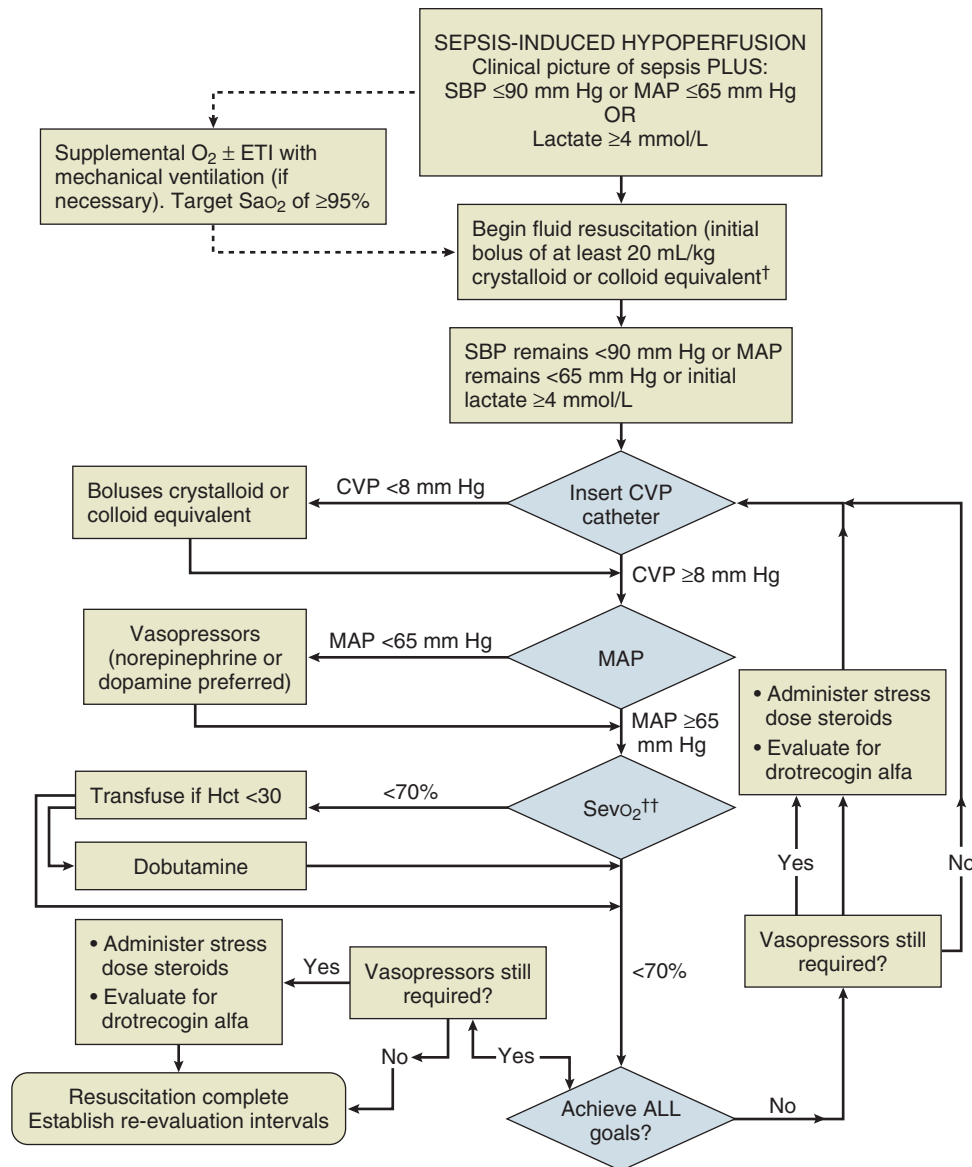

CONCLUSIONS

Resuscitation of critically ill patients is a complex process. Several simple steps need to be taken to ensure delivery of an appropriate level of resuscitation. First, the patient

should attain an optimal level of preload. This is best achieved by identifying the group of patients who are likely to benefit from volume loading and then providing this intervention, while at the same time not giving excess intravascular volume to patients who are unlikely to benefit from it. If it is impossible to predict which patients will benefit, then the fluid should be given under tightly controlled circumstances in the form of a fluid challenge with close monitoring of the circulation. After appropriate volume resuscitation, the circulation of some patients will still be inadequate for their metabolic demands. These patients may then benefit from either a reduction in oxygen requirements or an increase in oxygen delivery. This approach necessitates the monitoring of the circulation and the metabolic status.

KEY POINTS

- Isolated measurements of either right atrial pressure or pulmonary artery pressure are not good markers for identifying patients who will respond to a fluid challenge.
- Dynamic measurements of pulse or stroke volume variation can predict volume responsiveness with a high degree of sensitivity and specificity.
- No “normal” cardiac output can be specified for any patient, so cardiac output must be compared with other markers of metabolic status.
- Cardiac output can be measured by a number of techniques. Less important than how it is measured is how this knowledge is applied.

[†] In circumstances where MAP is judged to be critically low, vasopressors may be started at any point in this algorithm.

^{††} If pulmonary artery catheter is used, a mixed venous O₂ saturation is an acceptable surrogate and 65% would be the target.

Figure 3.8 Rivers protocol for hemodynamic management in severe sepsis or septic shock. This treatment algorithm provides a framework for the management of the hemodynamic disturbances associated with severe sepsis and septic shock. CVP, central venous pressure; ETI, endotracheal intubation; Hct, hematocrit; MAP, mean arterial pressure; SaO₂, arterial oxygen saturation; SBP, systolic blood pressure; ScvO₂, saturation of central venous oxygen.

Pulmonary Artery Occlusion Pressure and Partial Occlusion

Does the Use of a Pulmonary Artery Catheter Improve Outcome?

ARTERIAL CATHETERS

WHAT DO THEY OFFER?

The placement of an arterial catheter permits (1) reliable and continuous monitoring of arterial pressure and (2) repeated blood sampling. Analysis of the arterial pulse pressure curve may also have other applications, including assessment of fluid responsiveness and estimation of cardiac output. The appearance of arterial pressure waves will vary according to the site at which the artery is sampled. As the arterial pressure wave is conducted away from the heart, three effects are observed: The wave appears narrower; the dicrotic notch becomes smaller; and the perceived systolic and pulse pressures rise and the perceived diastolic pressure falls.

ARTERIAL PRESSURE MEASUREMENT

The optimal range of arterial pressure depends on individual patient characteristics, on underlying diseases, and also on treatment. Hence, it is impossible to give an optimal range of arterial pressure that is applicable in all patients. When arterial pressure needs to be evaluated accurately, oscillometric measurements become unreliable,¹ and insertion of an arterial catheter is indicated.

Four potential indications for insertion of an arterial catheter for measurement of arterial pressure are recognized:

1. *Hypotensive states associated with (a risk of) altered tissue perfusion.* Hypotension that is resistant to fluid administration requires the administration of vasopressor agents, and invasive measurement of arterial pressure is then necessary to titrate this form of therapy. Norepinephrine is the vasopressor agent most commonly used in this setting. A mean arterial pressure (MAP) of 65 to 70 mm Hg is usually targeted, but this level must be adapted to the individual patient and the clinical scenario; in particular, elderly patients with atherosclerotic disease may require higher levels than younger individuals with normal arteries.
2. *Intravenous vasodilator therapy.* Vasodilating therapy (e.g., nitrates and hydralazine) is a mainstay in the management of heart failure, because it can increase cardiac output. Close monitoring of arterial pressure is essential to avoid excessive hypotension.
3. *Severely hypertensive states.* Extreme hypertension may result in organ impairment, especially of the brain and the heart. Sodium nitroprusside or calcium entry blockers usually are used to lower arterial pressure, and careful, accurate monitoring is essential to titrate the antihypertensive therapy.
4. *Induction of hypertension.* Hypertension is sometimes induced in patients with neurologic diseases. Severe cerebral edema with intracranial hypertension, in particular, requires vasopressor support to maintain cerebral perfusion pressure (the gradient between the MAP and the

Figure 4.1 The systolic pressure variation (SPV) is the difference between the maximum and the minimum systolic blood pressures during one ventilatory cycle (A). The SPV is the sum of the ΔDown (B) and the ΔUp (C). (From Perel A, Pizov R, Coté S: Systolic blood pressure variation is a sensitive indicator of hypovolemia in ventilated dogs subjected to graded hemorrhage. *Anesthesiology* 1987;67:498.)

intracranial pressure); likewise, hypertension may be used to treat or prevent the development of vasospasm secondary to subarachnoid hemorrhage, as part of the so-called triple-H therapy (hypertension, hypervolemia, hemodilution). Norepinephrine usually is used for this purpose.

FLUID RESPONSIVENESS

Variations in arterial pressure during positive-pressure ventilation have been used as a measure of fluid responsiveness. The transient increases in intrathoracic pressure influence venous return in patients who are likely to respond to fluid administration. This fluctuation in ventricular filling will translate into fluctuations in arterial pressure a few beats later. Accordingly, the greater the degree of systolic arterial pressure, or pulse pressure, variation during the respiratory cycle, the greater will be the increase in cardiac output in response to fluid administration (Fig. 4.1). However, this observation is valid primarily in patients without spontaneous respiratory movements and without significant arrhythmias, and only when a sufficient tidal volume is applied.^{2,3}

CARDIAC OUTPUT ASSESSMENT

The pulse contour analysis also can serve to estimate cardiac output less invasively than with the pulmonary artery catheter (PAC). Because the only determinants of arterial pressure are the stroke volume and the resistance and compliance factors of the blood and arteries, analysis of the pulse contour trace can help to monitor cardiac output over time. This can be done with regular calibrations whenever changes in vascular tone or blood volume occur, or even in the absence of calibration. These measurements are still approximations, so further technological developments can be expected to improve accuracy.

BLOOD SAMPLING

The presence of an arterial catheter can greatly facilitate blood sampling, especially in terms of enabling easy access

Figure 4.2 Schematic representation of an arterial pressure tracing showing that the pulse pressure increases as arterial size decreases.

to the circulation for regular monitoring of blood gases, such as may be required in severe respiratory failure or with acute metabolic alterations. Sensors can measure blood gases continuously, but widespread use of such sensors is limited by their cost.

ACCESS

For placement of arterial catheters, usually the radial artery is used. The femoral artery can be easily cannulated and gives a better signal, but presence of a femoral catheter interferes more with patient mobility and warrants concern about infection.⁴ Use of other sites, such as the brachial or the axillary artery or even the dorsalis pedis artery,⁵ can be considered. An important point to keep in mind is that the pulse pressure increases from the core to the periphery. In other words, the systolic pressure is overestimated in smaller arteries (Fig. 4.2). Hence, it may be better to rely more on mean values than on systolic or diastolic pressures.

COMPLICATIONS

The most feared complication with use of arterial catheters is ischemia. With any suspicion of ischemia, the catheter must be removed immediately. Allen's test, to determine occlusive arterial lesions distal to the wrist, is unreliable and is no longer widely used. The accidental disconnection of arterial lines can be associated with severe hemorrhage and even exsanguination. Infectious complications are rare.

CENTRAL VENOUS CATHETERS

WHAT DO THEY OFFER?

The central venous catheter can facilitate fluid administration. It also allows measurement of the central venous pressure (CVP) and enables access to central venous blood for sampling.

FLUID ADMINISTRATION

The large-bore central venous catheter allows fluids to be administered fast and reliably in the presence of acute hemorrhage. Placement of a central catheter is therefore essential in patients with hemorrhage due to polytrauma or with other forms of acute bleeding. It also allows irritant or

hypertonic fluids to be administered, such as parenteral solutions, potassium-enriched solutions, and some therapeutic agents. Central venous lines also can be convenient in patients who need prolonged intravenous therapy when peripheral venous access becomes problematic.

MEASUREMENT OF CENTRAL VENOUS PRESSURE

CVP is identical to right atrial pressure (RAP) (in the absence of vena cava obstruction) and to right ventricular (RV) end-diastolic pressure (in the absence of tricuspid regurgitation). It is thus equivalent to the right-sided filling pressure. CVP is determined by the interaction of cardiac function and venous return, which is itself determined by the blood volume and the compliance characteristics of the venous system. Hence, an elevated CVP can reflect an increase in blood volume as well as an impairment in cardiac function. Because the CVP evaluates the right-sided filling pressures, CVP can be increased in the presence of pulmonary hypertension, even if left ventricular (LV) function is normal. The normal value in healthy persons is very low, not exceeding 5 mm Hg. Thus, the CVP value may not be much lower than normal in the presence of hypovolemia. In general, a CVP below 10 mm Hg can be considered to indicate that the patient is more likely to respond to fluid resuscitation, but exceptions to this rule exist. A high CVP suggests a certain blood volume but does not guarantee sufficient LV filling.

Clinically, CVP can be assessed by evaluation of the degree of jugular distention⁶ or liver enlargement. A single CVP measurement is not very useful and is not a good indicator of a positive response to fluids; an increase in CVP without a concurrent increase in cardiac output is not only useless but also harmful, because it will lead to increased edema formation.

ACCESS TO BLOOD IN SUPERIOR VENA CAVA

Measuring the central venous oxygen saturation ($ScvO_2$) is a surrogate for measurement of the true mixed venous oxygen saturation ($S\bar{v}O_2$). Although absolute values of $ScvO_2$ are not identical to single $S\bar{v}O_2$ values, trends in $ScvO_2$ over time follow the same pattern as trends in $S\bar{v}O_2$, making $ScvO_2$ a useful measure in patients who do not require an arterial catheter.⁷ $ScvO_2$ can be obtained either intermittently (by withdrawal of blood samples) or continuously (with the use of a catheter equipped with fiberoptic fibers).

TRACE ANALYSIS

Analysis of the CVP waveform can provide some interesting information. In particular, a large y descent indicates a restrictive cardiac state, but not all restrictive patterns are associated with this finding.

ACCESS

The central venous catheter generally is introduced via the internal jugular vein; the subclavian vein also can be used, although the risk of pneumothorax may be somewhat higher with this route. Peripherally inserted central catheters can also be placed, via the cephalic vein, basilic vein, or brachial vein. Introduction of a femoral catheter through the abdominal inferior vena cava to the right atrium can also yield reliable CVP measurements.⁸ The use of femoral

catheters, however, is associated with a greater risk of infections and thrombophlebitis.⁹

COMPLICATIONS

Complications of central venous catheterization are related primarily to puncture of the central vein: Hemothorax can be life-threatening, especially in the presence of severe respiratory failure. In the presence of unilateral pathology, the catheter must be introduced on the affected side. Arterial puncture resulting in a local hematoma is not uncommon, but hematoma formation usually is without major consequences. Bedside ultrasonography can help guide the introduction of the catheter into the vein. Excessive advancement of a long catheter in a small patient can result in arrhythmias; such arrhythmias have been described with advancement of the catheter tip into the right ventricle, but this problem can be identified by the presence of an RV trace on the monitor display.

Catheter-related infections constitute the major long-term complication. Adherence to basic hygiene guidelines can decrease the incidence of catheter-related sepsis. Triple-lumen catheters may be associated with a higher incidence of catheter-related infection,¹⁰ primarily as a result of increased catheter manipulation. The use of antimicrobial-coated catheters may decrease the risk of infections,¹¹ but fears remain about the risks of development of resistant organisms.¹² Routine replacement of catheters after 3 to 7 days is not recommended.¹³

PULMONARY ARTERY CATHETERS

WHAT DO THEY OFFER?

PACs allow collection of data on right atrial, pulmonary artery, and pulmonary artery occlusive pressures (Fig. 4.3); flow (cardiac output); and oxygenation ($S\bar{v}O_2$).

PRESSURES

Right Atrial Pressure

As indicated earlier, the RAP is identical to the CVP in the vast majority of cases.

Pulmonary Artery Occlusion Pressure

When the balloon on the catheter is inflated, it causes an obstruction (becomes wedged) in a small branch of the pulmonary artery, interrupting the flow of blood locally (but blood flow continues normally in the rest of the pulmonary circulation), so that (assuming the absence of an abnormal obstacle) a continuous column of blood is present between the tip of the PAC and the left atrium. This pulmonary artery occlusion pressure (PAOP), or pulmonary artery wedge pressure (PAWP), generally reflects the left atrial pressure well. Nevertheless, a number of steps must be taken to ensure the adequacy of the measurement.

A first question is whether the PAOP reflects the pressure in the pulmonary veins and not the alveolar pressure. The tip of the catheter should be in a West zone III position, where a continuous column of blood exists between the

Figure 4.3 Pressure waveforms. **A**, The normal right atrial (RA) tracing. The a wave is the RA pressure rise resulting from atrial contraction and follows the P wave of the electrocardiogram (ECG). On simultaneous ECG and RA tracings it usually occurs at the beginning of the QRS complex. The c wave, caused by closure of the tricuspid valve, follows the a wave and is coincident with the beginning of ventricular systole. Atrial relaxation (x descent) is followed by a passive rise in RA pressure resulting from atrial filling during ventricular systole and occurs during the T wave of the simultaneously recorded ECG. The y descent reflects the opening of the tricuspid valve and passive atrial emptying. **B**, The normal right ventricular (RV) tracing. The sharp rise in RV pressure (1) is due to isometric contraction and is followed by a rapid pressure decrease (2) as blood is ejected through the pulmonary valve. This rapid ejection is followed by a phase of more reduced pressure decrease, which is often reflected in a small step in the downslope of the RV pressure waveform (3). The subsequent sharp decline in RV pressure (4) occurs as a result of isometric relaxation and is noted once the RV pressure falls below the pulmonary artery (PA) pressure (with consequent closure of the pulmonary valve). As RV pressure falls below RA pressure, the tricuspid valve opens, and passive refilling (5) of the right ventricle occurs, followed by atrial contraction, causing a biphasic wave of ventricular filling to appear on the RV tracing (6). **C**, The normal pulmonary arterial waveform. A pulmonary artery systolic elevation is caused by ejection of blood from the right ventricle, followed by a decline in pressure as RV pressure falls. As RV pressure falls below pulmonary artery pressure, the pulmonary valve closes, which causes a momentary rise in the declining pulmonary artery pressure. This is the dicrotic notch characteristic of the pulmonary arterial (and also the systemic arterial) waveform. The pulmonary artery systolic wave usually occurs in synchrony with the T wave of the ECG. Pulmonary artery diastolic pressure (PADP) does not fall below RA pressure and therefore is higher than right ventricular end-diastolic pressure (RVEDP): it is an approximation to left ventricular end-diastolic pressure (LVEDP). **D**, The normal pulmonary artery occlusion pressure (PAOP) waveform. The waveform of the pulmonary capillary wedge pressure (PCWP) is subject to the same mechanical variables as the RA waveform, but because of the damping that occurs through the pulmonary circulation, the waves and descents often are less distinct. Similarly, the mechanical events are recorded later in the cardiac cycle, as seen on the ECG. Thus, the a wave is not seen until after the QRS complex, and the v wave occurs after the T wave of the ECG. The PCWP is a closer approximation to LVEDP than is PADP. (From Grossman W: Cardiac catheterization. In Braunwald E (ed): Heart Disease: A Textbook of Cardiovascular Medicine, 3rd ed. Philadelphia, WB Saunders, 1992.)

catheter tip and the left atrium (Fig. 4.4). These considerations are less important with fluid optimization and with today's lower positive end-expiratory pressures (PEEPs).

To exclude a possible influence of airway pressure on PAOP readings, the changes in PAOP can simply be compared with the changes in pulmonary artery pressure (PAP) during the respiratory cycle. If PAOP reflects the pressure within the pulmonary veins, these changes should be identical, because the pulmonary artery and vein should be subjected to identical changes in intrathoracic pressures. If, on the other hand, the catheter tip is not in a West zone III, the changes in PAOP will be more significant than the changes in PAP. In these latter conditions, either fluid administration or some reduction in the PEEP level may abolish the differences.

The next question is whether the measured pressure is truly a transmural pressure—that is, the pressure difference between the vascular structures and the environmental structures. In other words, will changes in surrounding intrathoracic pressures influence the pressures measured? In the case of intrathoracic pressures, the changes in pleural pressure are particularly relevant. Hence, all measurements should be performed at end-expiration, when the pleural pressure is closest to zero. A marked fall in intrapleural pressure, as with a Mueller maneuver (forced inspiration against resistance), may dramatically increase the transmural pressures. A more common problem in the intensive care unit (ICU) is the increase in pleural pressure due to

positive-pressure ventilation, sometimes with high PEEP levels.

One method of combating this problem could be to subtract the esophageal pressure from the measured PAOP, but this approach has a number of technological limitations. Simple disconnection of the respirator to measure PAOP after obtaining an equilibration state is not recommended, because the measured PAOP will not represent the real value when PEEP is applied. A better method consists of measuring the lowest (nadir) PAOP, within seconds after a very transient disconnection from the ventilator, to identify the true transmural pressure before a new equilibrium is reached.¹⁴ Such a maneuver suppresses the high intrathoracic pressure and eliminates the influence of the extramural pressure, but the values obtained may not be valid in the presence of intrinsic PEEP. Other methods have been suggested, some relatively sophisticated¹⁵ and others more simple, involving subtraction of approximately one third of the PEEP level from the measured PAOP, for example. The question is whether this is really so important, because absolute PAOP values are not very helpful.

In respiratory failure, PAOP does not represent true capillary pressure, which may be somewhat higher. The true capillary pressure may be estimated from the measurement of the intersection point of the rapid and slow pressure decay curves recorded after a rapid interruption of the blood flow; such measurements of capillary pressure are possible from the pressure trace. This pressure is

Figure 4.4 The position of the pulmonary artery catheter tip in relation to the zones of the theoretical lung model described by West. For pulmonary artery occlusion pressure (PAOP) to be a valid estimate of “left heart” filling pressure, a continuous column of blood must exist between the catheter tip and the left atrium. In zones I and II, pulmonary vasculature is either totally or partially compressed by the intra-alveolar pressure, and measurements of PAOP will be misleading. PA, alveolar pressure; Pa, pulmonary artery pressure; Pv, pulmonary venous pressure. (From Marini JJ: Respiratory Medicine and Intensive Care for the House Officer. Baltimore, Williams & Wilkins, 1991.)

well correlated with extravascular lung water in animal experiments. The need to know these values is questionable, however, because the primary goal remains to keep these hydrostatic pressures as low as possible while maintaining adequate cardiac output.

PAOP may not adequately reflect LV end-diastolic pressure. It may be lower in patients with aortic regurgitation or higher in the presence of significant tachycardia or mitral valve disease. LV end-diastolic pressure may not even accurately predict LV end-diastolic volume. This was already demonstrated many years ago with radionuclide techniques.¹⁶ Preload is more directly defined as the end-diastolic volume. A stiff, noncompliant ventricle can result in a relatively high end-diastolic pressure for a given end-diastolic volume. An evaluation of end-diastolic volumes can be obtained less invasively with echocardiographic techniques. Likewise, the use of transthoracic thermodilution techniques allows the estimation of intrathoracic blood volume and global end-diastolic volumes. However, these assessments of end-diastolic volumes do not give additional information about the likelihood of fluid responsiveness.

In sum, then, a given level of cardiac filling pressures does not provide much information about fluid responsiveness, but monitoring can be very helpful to guide a fluid challenge.¹⁷ During fluid administration, the goal is to obtain a significant increase in cardiac output (by the Frank-Starling mechanism), with the least increment in cardiac filling pressures, in order to minimize the risk of edema formation. The goal is not to keep the cardiac filling pressures within predefined arbitrary limits; rather, PAOP is a direct

Figure 4.5 Ventricular function curve depicting the difference between ventricular dysfunction (decrease in the ventricular ejection fraction [EF] but preservation of stroke volume) and ventricular failure (defined as the inability of the heart to pump enough flow). The EF, the ratio between stroke volume and end-diastolic volume, is represented by the *dashed lines*; it is decreased in all cases.

determinant of edema formation in the lungs. The key principle is to keep the PAOP as low as possible, provided that all of the other organs are happy.

Pulmonary Artery Pressures

Normally the pulmonary vasculature is a low-resistance circuit, so that the diastolic PAP should be equal to or only slightly higher than the PAOP. An increased pressure gradient between the diastolic PAP and the PAOP indicates active primary pulmonary hypertension related to pulmonary vascular changes (hypoxia) or diseases (primary pulmonary artery hypertension). Pulmonary hypertension may result in RV dilation with septal shifts that may compromise LV function.

CARDIAC OUTPUT

The reference method for measurement of cardiac output is use of the Fick equation; however, this equation is difficult to apply in practice. The indicator dilution technique has been used instead. Indocyanine green clearance has been used for many years, but this method is time-consuming and quite difficult to perform. The thermodilution technique developed by Ganz is a convenient technique which today allows the almost continuous measurement of cardiac output. The presence of tricuspid insufficiency is the major limitation to this technique. Other techniques, including transpulmonary and lithium dilution techniques, have been developed but are somewhat less precise.

The thermodilution technique estimates cardiac output over several cardiac cycles, whereas other techniques, including those based on pulse contour analysis, may assess beat-to-beat variations. These techniques may be useful for estimating the influence of changes in intrathoracic pressures on the stroke volume variation, an estimate of fluid responsiveness.

RIGHT VENTRICULAR VOLUMES

The use of a modified PAC equipped with a fast response thermistor also allows evaluation of the right ventricular ejection fraction (RVEF) (Fig. 4.5). With knowledge of the stroke volume, it becomes easy to calculate the end-systolic and end-diastolic volumes. This measurement can

be particularly useful in the presence of RV failure, but this also is a situation in which the measurement is least reliable: tricuspid regurgitation secondary to pulmonary hypertension.

MIXED VENOUS OXYGEN SATURATION

$\text{S}\bar{\text{v}}\text{O}_2$ represents the balance between oxygen consumption and oxygen supply. According to the Fick equation:

$$\text{VO}_2 = \text{cardiac output} \times (\text{CaO}_2 - \text{C}\bar{\text{v}}\text{O}_2)$$

where VO_2 is oxygen uptake and CaO_2 and $\text{C}\bar{\text{v}}\text{O}_2$ are the arterial and mixed venous oxygen content, respectively. If the dissolved oxygen in the blood is neglected for the purposes of calculation, then

$$\text{VO}_2 = \text{cardiac output} \times \text{Hb}(\text{SaO}_2 - \text{S}\bar{\text{v}}\text{O}_2) \times \text{C}$$

and

$$\text{S}\bar{\text{v}}\text{O}_2 = \text{SaO}_2 - (\text{VO}_2 / \text{cardiac output} \times \text{Hb} \times \text{C})$$

where Hb is hemoglobin.

Accordingly, a decrease in $\text{S}\bar{\text{v}}\text{O}_2$ can reflect either a decrease in SaO_2 (hypoxemia), anemia, or a relative inadequacy of cardiac output in relation to the oxygen demand of the tissues.

$\text{S}\bar{\text{v}}\text{O}_2$ can be measured continuously using catheters equipped with fiberoptic fibers, and measurements are helpful to guide therapy. ScvO_2 has been proposed as a surrogate for $\text{S}\bar{\text{v}}\text{O}_2$, but the relationship between ScvO_2 and $\text{S}\bar{\text{v}}\text{O}_2$ is rather vague. Indeed, the ScvO_2 is lower than $\text{S}\bar{\text{v}}\text{O}_2$ in healthy conditions (as a result of the low O_2 extraction by the kidneys) but is higher than $\text{S}\bar{\text{v}}\text{O}_2$ in critically ill patients (because of relative increase in O_2 extraction in the kidneys and in the gut).¹⁸ Moreover, O_2 extraction is high in the coronary circulation, and this is missed in the measurement of ScvO_2 .

DERIVED VARIABLES

Hemodynamic assessment can include a number of derived variables, including resistance, ventricular stroke work, oxygen transport, oxygen consumption, and venous admixture, as described next.

Resistance. In steady-flow conditions, Ohm's law indicates that resistance is the ratio between the pressure drop and the flow in the system. In the pulmonary circulation, the inflow pressure would be the mean PAP and the outflow pressure would be PAOP; for the systemic circulation, these would be the MAP and the CVP, respectively. In either case, flow would be cardiac output. This approach is limited, however, by the fact that the extrapolated intercept of the PAP–cardiac output relationship represents the average closing pressure of the small pulmonary arterioles, and the slope represents the upstream arterial resistance. Accordingly, the increased PAP in pulmonary hypertension can be explained by both an increase in pulmonary vascular closing pressure and an increase in vascular tone, and pulmonary vascular resistance (PVR) is not a good reflection of vasomotor tone in the pulmonary vasculature. Pulmonary hemodynamics are therefore best assessed by altering blood flow to better evaluate this relationship (Fig. 4.6).

Calculation of systemic vascular resistance (SVR) is not very helpful either. It is better to base clinical decisions on

Figure 4.6 Relationship between pressure and blood flow, illustrating the limitations in the calculation of the vascular resistance. Note that the line defining that relationship does not go through the origin, because the pressure is not zero in the absence of blood flow.

primary variables. Simply stated, a relatively high cardiac output in relation to arterial pressure reflects a low SVR state, whereas a relatively low cardiac output reflects a high SVR state.

Ventricular Stroke Work. The work developed by the ventricles is determined by the ventricular work as derived from the product of flow and the pressure generated. The relationship between stroke work and the respective filling pressure represents a better assessment of contractility than does the stroke volume. LV stroke work index (LVSWI) can be calculated using the equation

$$\text{LVSWI} = \text{SVI}(\text{MAP} - \text{PAOP}) \times 0.0136$$

where SI represents the stroke volume index.

Oxygen-Derived Variables. Oxygen transport can be assessed as the product of cardiac output and the arterial oxygen content, according to the equation

$$\begin{aligned} \text{DO}_2 &= \text{cardiac output} \times \text{CaO}_2 \\ &= \text{cardiac output} \times ([\text{Hb}] \times \text{SaO}_2 \times 1.39) + 0.0031 \times \text{PaO}_2 \end{aligned}$$

Calculations of this variable benefit from combining measurements of cardiac output, Hb, and SaO_2 but have the limitation that the corresponding oxygen demand is unknown. Some studies suggested that maintaining supra-normal DO_2 in the perioperative period or early after trauma may result in better outcomes.

Oxygen consumption also can be calculated from the product of cardiac output and the arteriovenous oxygen difference, according to the formula

$$\text{VO}_2 = \text{cardiac output} \times (\text{CaO}_2 - \text{C}\bar{\text{v}}\text{O}_2)$$

where $\text{C}\bar{\text{v}}\text{O}_2$ is calculated in the same way as for CaO_2 , using the SvO_2 instead of the SaO_2 .

The difficulty is in evaluating the oxygen requirements (or the oxygen demand) of the body. VO_2 assessment may perhaps be useful to evaluate the caloric need of the critically ill patient.

Figure 4.7 Diagram illustrating the relationship between cardiac index and O₂ extraction. Four typical examples are given: hyperkinetic state (A), anemia (B), low cardiac output state (C), and profound anesthesia (D).

The calculation of oxygen extraction (oxygen extraction ratio, or O₂ER) is accomplished by determining the ratio of VO₂ to DO₂, or in a simplified way:

$$\begin{aligned} \text{O}_2\text{ER} &= \text{VO}_2 / \text{DO}_2 = (\text{CaO}_2 - \text{CvO}_2) / \text{CaO}_2 \\ &= (\text{SaO}_2 - \text{SvO}_2) \text{Hb} / \text{SaO}_2 \times \text{Hb} \\ &= (\text{SaO}_2 - \text{SvO}_2) / \text{SaO}_2 \end{aligned}$$

Accordingly, when SaO₂ is close to 100%, in the absence of hypoxemia, O₂ER mirrors SvO₂. Its calculation can be useful in the presence of hypoxemia, when SaO₂ is decreased. Also, the relationship between cardiac output and O₂ER can be helpful to compare the central and the peripheral components of oxygen delivery (Fig. 4.7). This relationship is independent of Hb, so it can be helpful in evaluating the cardiovascular status in the presence of anemia.¹⁹

Venous Admixture. Venous admixture can be calculated by the Berggren equation:

$$\begin{aligned} \text{Qs} / \text{Qt} &= \text{Cc}'\text{O}_2 - \text{CaO}_2 \\ &\quad \text{Cc}'\text{O}_2 - \text{CvO}_2 \end{aligned}$$

in which Qs is shunt flow, Qt is total pulmonary blood flow, and Cc'O₂ represents the capillary oxygen content (assuming an oxygen saturation of 100%). This may help to assess the effects of various interventions (PEEP or other respiratory conditions, administration of vasoactive agents) on pulmonary hemodynamics.

COMPLICATIONS

Complications of pulmonary artery catheterization can be divided into seven categories as listed in Box 4.1. Many of these can be prevented, and most are relatively uncommon.

Complications of venous access are the same as for the insertion of a central venous catheter. Arrhythmias are

Box 4.1 Complications of Pulmonary Artery Catheter Insertion

- Complicated vascular access (pneumothorax, hematoma)
- Arrhythmias (e.g., heart block, ventricular tachycardia/fibrillation)
- Catheter knotting
- Pulmonary thrombosis and infarction
- Endothelial or valvular damage
- Colonization and bacteremia
- Pulmonary artery rupture

common but usually are without major consequence, except in moribund patients. It has been suggested that lidocaine should be given prophylactically in predisposed patients, but this usually is not necessary. Likewise, complete atrio-ventricular block may develop in patients with left bundle branch block, but this is exceptional. Knot formation will be rare if the catheter is advanced carefully and if its presence in the pulmonary artery is confirmed before further advancement into the right ventricle. In particular, care should be taken not to advance the catheter by more than 30 to 35 cm into the right ventricle. Thrombotic complications have become rare with the development of heparin-coated catheters. The appearance of an infiltrate beyond the tip of the PAC on the chest film should suggest an evolving thrombotic event, which should lead to consideration of the withdrawal of the catheter. Endothelial lesions have been found at autopsy, but their clinical relevance is doubtful. Endocarditis is very rare. Valvular damage may occur as a result of improper handling of the catheter (in particular, its withdrawal with the balloon still inflated). Catheter-related infections remain a risk, but they do not seem to be any more common than with central venous catheters.

Pulmonary artery rupture is the most feared complication: Although it is exceptionally rare, it is associated with a high mortality rate. The usual cause is overinflating the balloon in the presence of resistance to inflation, particularly in the presence of preexisting PAH; other, less common causes are shown in Figure 4.8. The cardinal sign of rupture is the development of hemoptysis. The reaction to this event should not be to pull out the catheter entirely, but rather to withdraw it slightly and then inflate the balloon. If the hemorrhage does not stop, a thoracotomy may be necessary to repair the pulmonary artery.

TECHNICAL LIMITATIONS

Invasive measurements of pressures are based on fluid-filled systems with disposable transducers. The transducer includes a deformable membrane with a Wheatstone bridge modifying the electrical resistance and, correspondingly, the intensity of a current. Reliability is ensured by the excellent linearity between the pressure signal and the electrical signal generated by the transducer, in a range of frequency values largely exceeding the range of frequencies found in the human body.

Reliability is less secure in the intermediary system made of tubes and stopcocks along the extent of the pressure

Figure 4.8 Possible mechanisms of pulmonary artery rupture (other than the most common cause, overinflating the balloon in the presence of resistance to inflation). (From Barash PG, Nardi D, Hammond G, et al: Catheter-induced pulmonary artery perforation. Mechanisms, management, and modifications. J Thorac Cardiovasc Surg 1981;82:5.)

system. These can modify the morphology of the trace, resulting in damping. Motion artifacts can further complicate the tracings. The presence of air bubbles also may alter the signal. Use of fluid-filled catheters to measure pressures provides reliable estimates of mean vascular pressures.

Three steps must be followed to guarantee reliable measurements:

1. The first step is appropriate zeroing, which is accomplished by opening the transducer to atmospheric pressure (taken as the zero value). All pressures must be measured with reference to an arbitrary reference point. This zero reference pressure level should ideally be where it is least influenced by location on the body. In humans, it is thought to be at the level of the right atrium, so the reference level usually is placed in the midchest (midaxillary) position at the level of the fourth intercostal space. In healthy persons, the CVP referred to that region does not change with supine versus upright position. An alternative reference is 5 cm vertically below the sternal angle. Obviously, errors in zeroing are relatively more important for measurements of cardiac filling pressures than for arterial pressure measurements, because the errors are quantitatively identical but proportionally greater.
2. The second step is calibration, which is now done automatically by today's electronic systems.
3. The third step is ensuring the good quality of the trace. Shaking the catheter should result in large pressure variations on the screen. A damped system will underestimate systolic pressures. The liquid column should be continuous, without air bubbles in the system. Excessive tubing length, or multiple stopcocks and connectors, may decrease the resonant frequency, resulting in "whipped" traces. Likewise, the presence of bubbles must be carefully avoided. Transient flushing should be

followed by an abrupt return of the pressure trace to its actual value.

APPLICATIONS: DIAGNOSIS VERSUS MONITORING

Today the PAC is more useful in guiding therapy rather than in identifying abnormalities, this latter role having largely been taken over by noninvasive, mainly echocardiographic techniques (Table 4.1). In the past, analysis of waveforms was used—for example, the abnormal v waves of mitral regurgitation. Likewise, an increase of all pressures to identical levels should suggest pericardial tamponade. These findings should still alert the clinician to possible abnormalities, but echocardiographic techniques have largely replaced the use of the PAC for identifying valvular disease. The use of echocardiographic techniques for monitoring, however, is hampered by the difficulty of keeping the probe in the esophagus for prolonged periods of time, and results are very operator dependent.

To illustrate the need to integrate different variables, rather than focusing on just one variable, some suggested applications follow:

- *Interpretation of a cardiac output value:* It is important to consider the four determinants of cardiac output (Fig. 4.9).²⁰ Interpretation should start by considering the stroke volume (cardiac output divided by heart rate) and relating this to an index of ventricular filling (PAOP) and an index of ventricular afterload (arterial and pulmonary artery pressures); an inotropic agent should be added only when preload and afterload have been optimized.
- *Fluid status:* Low cardiac filling pressures may be normal or reflect hypovolemia. The measurement of cardiac output and SvO_2 will help determine fluid needs. Indeed, hypovolemia typically is associated with a low

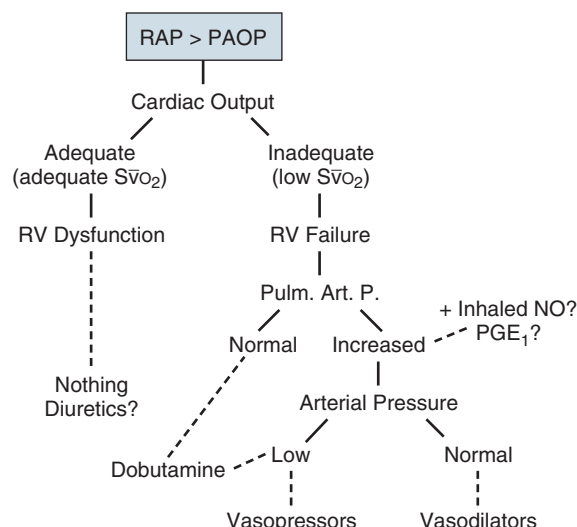

Table 4.1 Pulmonary Artery (PA) Catheterization Versus Echocardiographic Techniques for Management of Selected Disorders: Relative Value

Disorder	PA Catheterization		Echocardiography	
	Diagnosis	Monitoring	Diagnosis	Monitoring
Tamponade	+	++	+++	+
Hypovolemia	++	+++	++	+
Valvular disease	+	++	+++	+
Heart failure	++	+++	++	+
Right ventricular failure	++	+++	+++	++
Septic shock	+	+++	+	+

**Figure 4.9** The four determinants of cardiac output.**Figure 4.10** Interpretation of a low $S\bar{v}O_2$ (mixed venous oxygen saturation). CO, cardiac output; PAOP, pulmonary artery occlusion pressure; SaO_2 , arterial oxygen saturation; VO_2 , oxygen uptake.

cardiac output and a low $S\bar{v}O_2$ (Fig. 4.10). By contrast, hypervolemia in the presence of normal cardiac function will be manifested by high cardiac filling pressures associated with a relatively high cardiac output and normal or high $S\bar{v}O_2$.

- **Hemodynamic versus nonhemodynamic pulmonary edema:** The distinction between hemodynamic and nonhemodynamic types of lung edema no longer requires pulmonary artery catheterization; the clinical history and less invasive (e.g., echocardiographic) measurements usually are sufficient to separate the two. Nevertheless, invasive hemodynamic

**Figure 4.11** Interpretation of a reversed gradient between the right atrial pressure (RAP) and the pulmonary artery occlusion pressure (PAOP). NO, nitric oxide; PGE_1 , prostaglandin E_1 ; RV, right ventricular; $S\bar{v}O_2$, mixed venous oxygen saturation.

monitoring can reveal that patients thought to meet only the acute lung injury/acute respiratory distress syndrome (ALI/ARDS) criteria sometimes have unexpectedly high PAOP.²¹

- **RV dysfunction versus failure:** A reverse gradient between RAP and PAOP (i.e., a higher RAP than PAOP) indicates RV dysfunction or failure and usually is secondary to pulmonary hypertension, as will be immediately apparent from the measurements of pulmonary artery pressures. RV dysfunction is manifested by RV dilation (and thus a decrease in RVEF) with no limitation on cardiac output. This is the most common situation in patients with ARDS, who usually maintain a hyperkinetic state. Rather, RV failure refers to a state in which cardiac output is no longer sustained at adequate levels.²² These different entities are illustrated in Figure 4.11.
- **LV dysfunction versus failure:** Here the gradient between PAOP and RAP will be higher than the typical 3 to 5 mm Hg. As with the right ventricle, in LV dysfunction the ventricular volumes may increase (so the ejection fraction will decrease), but the cardiac output may be simultaneously preserved; such a situation may exist in septic shock.

LV failure is more common and is manifested by a decrease in cardiac output and SvO_2 .

ASSESSING EFFECTS OF INTERVENTIONS

The PAC can be used to monitor the effectiveness of various interventions:

- **Fluid challenge:** A fluid challenge technique is indicated whenever the benefit of fluid administration is in doubt.¹⁷ Ideally, fluid administration will result in increases in cardiac output and tissue perfusion without major increases in cardiac filling. An increase in PAOP in the absence of a significant change in cardiac output and SvO_2 indicates that fluid administration will only result in an increased risk of edema and should be discontinued.
- **Inotropic agents:** The use of inotropes aims to increase cardiac output and possibly decrease PAOP. Lack of an increase in cardiac output after administration of a β_1 -adrenergic inotropic agent indicates a desensitization of the β -adrenergic receptors and is associated with a worse prognosis.²³
- **Vasopressors:** The use of pure vasoconstrictors is expected to increase arterial pressure but also cardiac filling pressures. An excessive increase in cardiac filling pressures with use of such an agent suggests the need for addition of an inotropic agent (e.g., dobutamine).
- **Vasodilators:** The administration of vasodilators may rapidly reduce arterial pressure so that continuous arterial pressure monitoring is usually indicated. Moreover, a reduction in vascular tone in the presence of hypovolemia may reduce venous return and thus cardiac output.

CLINICAL INDICATIONS FOR PULMONARY ARTERY CATHETER INSERTION

The improvement in noninvasive diagnostic techniques means that today the PAC is used primarily for monitoring. Potential indications include the following:

- **Severe circulatory shock:** The PAC can be used to help guide fluid challenges and titrate inotropic agents. Shock due to hypovolemia (as in polytrauma or with other forms of massive bleeding) does not require insertion of a PAC, because management of such patients generally is quite straightforward.
- **RV failure:** The PAC can be used to monitor pulmonary artery pressures, the gradient between RAP and PAOP, cardiac output, and SvO_2 .
- **Acute respiratory failure due to pulmonary edema:** Whether lung edema is hemodynamic or nonhemodynamic, the strategy should be to keep the hydrostatic pressures as low as possible, but this requires measurements of cardiac output and SvO_2 to make sure the systemic circulation is not compromised.
- **Complex fluid management in the presence of impending renal failure:** Sometimes it is difficult to evaluate the fluid status in oliguric patients, in whom hypovolemia may compromise renal function but hypervolemia obviously must be avoided.
- **Dynamic assessment of cardiac function in specific conditions:** The best example is that of the patient who is difficult to

Figure 4.12 Schematic depiction of partial occlusion when the gradient between the pulmonary artery diastolic pressure (Ppad) and the pulmonary artery occlusion pressure (Ppao) is normal (top) or is increased (bottom). Arrow denotes balloon inflation. (From Leatherman JW, Shapiro RS: Overestimation of pulmonary artery occlusion pressure in pulmonary hypertension due to partial occlusion. Crit Care Med 2003;31:93-97.)

wean from mechanical ventilation, possibly owing in part to cardiac dysfunction.

PULMONARY ARTERY OCCLUSION PRESSURE AND PARTIAL OCCLUSION

Partial occlusion of the pulmonary artery in the presence of pulmonary hypertension may be difficult to recognize and can lead to significant overestimation of the PAOP, denoted Ppao on Figure 4.12. A useful clue to partial occlusion is occurrence of a substantial increase in the PAOP without a concomitant change in the pulmonary artery diastolic pressure, denoted Ppad on the figure. If the Ppad – PAOP gradient is normal and the underlying disease process would predict increased PVR, partial occlusion should be suspected. Partial occlusion may occur if a catheter is either too proximal or too distal in the pulmonary artery, and appropriate repositioning may be corrective. The best PAOP may be obtained in some circumstances by further advancing the catheter with the balloon fully inflated and at other times by retracting the catheter to the original pulmonary artery position and attempting to occlude with 1.0 to 1.2 mL of air, instead of full inflation. It is imperative never to inflate against resistance. Figures 4.12 and 4.13 offer further information on diagnosis and management of partial occlusion.

DOES THE USE OF A PULMONARY ARTERY CATHETER IMPROVE OUTCOME?

The use of the PAC has been challenged on the basis that it has not been shown to improve outcomes.^{21,24-26} An improvement in outcome, however, has not been demonstrated with other monitoring techniques either. Moreover, a number of studies have indicated that the use of the PAC can influence therapy.²⁷ If use of a PAC does not result in better outcomes, important and challenging questions arise about the beneficial effects of many therapeutic

Figure 4.13 Partial pulmonary artery occlusion pressure (Ppao) measured when 1.5 cc of air was used to inflate the catheter balloon (*left graph*); a much lower Ppao was obtained with a 1.0-cc inflation (*right graph*). Review of the chest roentgenogram revealed that the catheter tip was too peripheral, so it was withdrawn to a more proximal location. Ppa, pulmonary artery pressure. See text for definition of partial and best Ppao values. Scale in mm Hg. (From Leatherman JW, Shapiro RS: Overestimation of pulmonary artery occlusion pressure in pulmonary hypertension due to partial occlusion. *Crit Care Med* 2003;31:93-97.)

Table 4.2 Components and Common Errors in Hemodynamic Monitoring

Component	Common Errors
1. Measure	Catheter misplacement Errors in pressure measurements No consideration of SvO_2
2. Interpret	Interpretation of cardiac output without consideration of SvO_2 Neglect of PAP/PAOP gradient Neglect of inversed RAP/PAOP gradient
3. Apply	Treating as if the data were not available Giving diuretics for a high PAOP without other consideration

PAP, pulmonary artery pressure; PAOP, pulmonary artery occlusion pressure; RAP, right atrial pressure; SvO_2 , mixed venous oxygen saturation.

interventions in the ICU. Some evidence suggests that the use of the PAC may improve outcomes in the most severely ill subsets of critically ill patients.^{28,29} Errors in measurements from the PAC were identified many years ago,³⁰ and another consideration is the considerable interobserver variability in interpretation of PAC tracings.³¹ Clearly, not all ICU patients need a PAC and insertion should be reserved for complex cases.³² If a PAC is considered necessary, it is important to respect the three successive steps (Table 4.2): to take adequate and full measurements; to interpret the results correctly; and to apply the gathered information for the patient's benefit. Unfortunately, potential errors are associated with each step. Some of these issues can be addressed with better teaching and improved basic knowledge of hemodynamics and basic physiology.

KEY POINTS

- No simple guidelines for monitoring are available or applicable in all cases; monitoring should be tailored to each patient's needs.
- Each variable, taken individually, has limitations and is subject to error and difficulty in interpretation. Variables should be combined and integrated to provide a global picture of the clinical situation.
- A monitoring technique cannot improve outcome by itself; each of the three components of monitoring is important with any monitoring technique:
 - Accurate collection of data
 - Interpretation of the data
 - Application of the information obtained
- Cardiac output is an adaptive value that must constantly adjust to the oxygen requirements of the organs.
- Separation of the four determinants of cardiac output—heart rate, contractility, preload, and afterload—is useful to consider the various interventions that can be used to increase it.
- Measurements of mixed venous oxygen saturation are essential to interpret cardiac output measurements.
- The relationship between cardiac filling pressures and volumes is relatively weak. Pressure measurements are important, however, because pressures (rather than volumes) are the primary determinant of edema formation.
- The calculation of derived variables, such as vascular resistances, ventricular work, and oxygen-derived variables, is of limited usefulness.

CONCLUSIONS

Cardiac pacing and arrhythmia management are of paramount importance in the critical care setting. Whether or not arrhythmia is the primary concern, the critical care physician needs to be proficient in arrhythmia recognition, temporary pacing, and basic device troubleshooting of previously implanted cardiac devices. This chapter is meant to be a practical review of an admittedly broad and expansive

topic, focusing on issues that are most likely to arise on a day-to-day basis in the intensive care unit.

The following topics will be discussed: (a) indications for permanent pacing, (b) indications for temporary pacing, (c) conditions that are generally reversible or transient, where pacing is not typically required, (d) techniques for temporary pacing, including esophageal, transcutaneous,

epicardial, and transvenous modalities, (e) complications related to pacing, and (f) additional considerations related to permanent pacing.

INDICATIONS FOR PERMANENT PACEMAKER IMPLANTATION

Bradycardia is the most common indication for pacing and is a common finding during the clinical evaluation of healthy individuals, as well as patients who are ill. Bradyarrhythmias may be caused by either intrinsic dysfunction of the sinus node (SN) or atrioventricular (AV) conduction system, or may be due to a response of normal tissues to extrinsic factors. In some cases, even profound bradycardia may be asymptomatic and have no immediate or long-term consequences. When deciding if a permanent pacemaker is in the best interests of the patient, the physician must analyze the clinical status of the patient, as well as the specific cardiac rhythm disorder, while considering the risks and benefits of permanent pacing.

The American College of Cardiology Foundation (ACCF), the American Heart Association (AHA), and the Heart Rhythm Society (HRS) have jointly engaged in the production of guidelines for cardiac implantable electronic device (CIED) implantation, with publication of updated Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities in 2008.¹ These recommendations are primarily evidence-based, and this publication includes an extensive review of the literature on the topic. As with other guideline documents, recommendations are classified as class I, II, or III as follows:

- Class I: Benefit >>> Risk; the procedure/treatment *should* be performed/administered.
- Class II: Conditions for which there is conflicting evidence or divergence of opinion about the usefulness/efficacy of the procedure.
 - Class IIa: Benefit >> Risk; *it is reasonable* to perform the procedure/administer treatment, although additional studies with focused objectives are still needed.
 - Class IIb: Benefit ≥ Risk; the procedure/treatment *may be considered*, although additional studies with broad objectives are needed or additional registry data would be helpful.
- Class III: Risk ≥ Benefit; the procedure/treatment *should not* be performed/administered because it is not helpful and may be harmful.

The level of evidence or weight of evidence to support these recommendations is ranked as follows:

- Level of evidence A: Data derived from multiple randomized clinical trials or meta-analyses.
- Level of evidence B: Data derived from a single randomized trial or nonrandomized studies.
- Level of evidence C: Consensus opinion of experts, case studies, or standard of care.

Indications for permanent pacemaker implantation can be divided into the following categories: (1) pacing for bradycardia due to SN and AV node dysfunction; (2) pacing

for special conditions, such as carotid sinus hypersensitivity, neurocardiogenic syncope, and cardiac transplantation; (3) pacing for prevention and treatment of arrhythmias; and (4) pacing for hemodynamic indications, including cardiac resynchronization therapy (CRT) and hypertrophic cardiomyopathy (HCM). As SN and AV node dysfunction are the most common indications for permanent pacemaker implantation, and are the most commonly encountered problems that require pacing in the intensive care setting, these indications will be the main focus of this chapter.

PACING INDICATIONS FOR SINUS NODE DYSFUNCTION

“Sinus node dysfunction” (SND) may be due to a problem of SN impulse formation or propagation, and may present with sinus bradycardia, chronotropic incompetence, or sinus arrest. SND may also be associated with “tachy-brady syndrome,” in which rapidly conducted, paroxysmal atrial arrhythmias alternate with periods of sinus bradycardia or prolonged postconversion pauses.

SND is the most common cause of bradyarrhythmias in clinical practice. The typical age at the time of diagnosis of SND appears to be in the seventh or eighth decade of life, with a mean or median age of 71 to 74 years in randomized clinical trials evaluating pacemaker therapy.²⁻⁴ However, clinical manifestations of SND may occur at any age and may be secondary to any one of several potential causes, including destruction of the SN, ischemia, infarction, infiltrative disease, surgical trauma, autonomic dysfunction, or endocrinologic abnormalities.^{1,5}

Clinical manifestations of SND are diverse, and symptoms may include fatigue, reduced exercise tolerance, dyspnea on exertion, presyncope, lightheadedness, dizziness, or syncope. In the absence of any clearly reversible cause of bradycardia, the only effective treatment for symptomatic bradycardia in patients with SND is permanent pacing. [Box 5.1](#) outlines recommendations for permanent pacing in patients with SND.¹

PACING INDICATIONS FOR ACQUIRED ATRIOVENTRICULAR BLOCK

AV block refers to impairment of conduction of electrical impulses from the atria to the ventricles, and can occur at the level of the AV node, within the His-Purkinje system, or below the His-Purkinje system. In general, block at the level of the His-Purkinje system has a high risk of progression to complete heart block and carries a poor prognosis without pacemaker implantation.

Electrocardiographic classification of AV block includes first-degree, second-degree, and third-degree (complete) block. First-degree AV block (or first-degree AV delay) refers to a prolonged PR interval (>200 ms) without failure of conduction to the ventricle, and is usually due to delay of impulse conduction through the AV node or through atrial tissue. Second-degree AV block refers to failure of an atrial impulse to conduct to the ventricle, and this may be preceded by fixed or gradually lengthening PR intervals. Mobitz type I second-degree AV block (or Wenckebach block) is characterized by progressive PR interval prolongation prior

Box 5.1 Recommendations for Permanent Pacing in Sinus Node Dysfunction (SND)

Class I

1. Permanent pacemaker implantation is indicated for SND with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms. (Level of evidence: C)
2. Permanent pacemaker implantation is indicated for symptomatic chronotropic incompetence. (Level of evidence: C)
3. Permanent pacemaker implantation is indicated for symptomatic sinus bradycardia that results from required drug therapy for medical conditions. (Level of evidence: C)

Class IIa

1. Permanent pacemaker implantation is reasonable for SND with heart rate less than 40 beats/min when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented. (Level of evidence: C)
2. Permanent pacemaker implantation is reasonable for syncope of unexplained origin when clinically significant abnormalities of sinus node function are discovered or provoked in electrophysiologic studies. (Level of evidence: C)

Class IIb

1. Permanent pacemaker implantation may be considered in minimally symptomatic patients with chronic heart rate less than 40 beats/min while awake. (Level of evidence: C)

Class III

1. Permanent pacemaker implantation is not indicated for SND in asymptomatic patients. (Level of evidence: C)
2. Permanent pacemaker implantation is not indicated for SND in patients for whom the symptoms suggestive of bradycardia have been clearly documented to occur in the absence of bradycardia. (Level of evidence: C)
3. Permanent pacemaker implantation is not indicated for SND with symptomatic bradycardia due to nonessential drug therapy. (Level of evidence: C)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al. American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices); American Association for Thoracic Surgery; Society of Thoracic Surgeons. ACC/AHA/HRS 2008 Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2008;117:e350-e408.

to a nonconducted P wave, with a shorter PR interval on the conducted beat occurring after the blocked beat. Mobitz II second-degree AV block is characterized by a fixed PR interval prior to the dropped P wave, often associated with a wide QRS complex.

Mobitz I second-degree AV block is frequently benign and is most often localized to block within the AV node, although there are rare exceptions. Although Mobitz I second-degree AV block has a low risk of progression to complete heart block, Mobitz II second-degree AV block is a more severe

conduction disturbance with a higher risk of progression to complete heart block. Although the anatomic level of block for individuals with 2:1 AV block may be at the level of the AV node or below the AV node, the level of block is more likely to be below the His-Purkinje system if the QRS complex is wide. However, if a preexisting bundle branch block is present, the block may be either at the level of the AV node or below the AV node.

Third-degree AV block refers to absence of impulse conduction from the atria to the ventricles, and this may be congenital or acquired. Permanent pacing is often indicated for acquired complete block without reversible causes. AV block may also occur in patients with SND, and 20% of patients with SND will have some degree of AV block.⁴ In addition, following permanent pacemaker implantation for SND, the risk of developing AV block within 5 years of follow-up is 3% to 35%.⁶⁻⁹

Acquired AV block is most often due to aging or related to calcification of the conduction system. Ischemic heart disease, myocardial infarction, and traumatic surgical causes (such as cardiac valve surgery) are other common causes. Less common causes of AV block include infection (syphilis, Lyme disease, endocarditis), infiltrative disease (sarcoidosis, malignancy), neuromuscular disease, or drugs (beta blockers, calcium channel blockers, digoxin, or membrane-active antiarrhythmic agents).

Patients with AV block may be asymptomatic, or may have symptoms that vary from mild lightheadedness, dizziness, shortness of breath, or fatigue to presyncope and loss of consciousness. The decision regarding permanent pacemaker implantation should take into account whether or not symptoms are attributable to bradycardia, as well as the cause and “level” of AV block. Completely reversible causes of AV block, such as electrolyte disturbances or Lyme disease, should be excluded. Permanent pacing indications for acquired AV block are summarized in Box 5.2. Pacing indications for chronic bifascicular block and pacing for AV block associated with acute myocardial infarction are outlined in Boxes 5.3 and 5.4.

OTHER PERMANENT PACING INDICATIONS

In specific situations, permanent pacing may also be clinically indicated in some patients with carotid sinus hypersensitivity, neurocardiogenic syncope, or obstructive hypertrophic cardiomyopathy, and following cardiac transplantation.¹ Historically, antitachycardia pacemakers were occasionally utilized to treat recurrent supraventricular arrhythmias, but they are rarely used in contemporary practice with the availability of catheter ablation therapy. Pace termination of ventricular tachycardia is frequently utilized for the treatment of monomorphic ventricular tachycardia as part of implantable cardioverter-defibrillator (ICD) therapy, and can also be used to terminate frequent arrhythmia episodes using a temporary transvenous pacing system in the intensive care setting (Fig. 5.1).

Pacing may be useful in the prevention of pause-dependent, polymorphic ventricular tachycardia as well (Fig. 5.2). Permanent pacing is indicated for pause-dependent ventricular tachycardia, with or without QT prolongation (class I indication, level of evidence C), and is reasonable for high-risk patients with congenital long

Box 5.2 Recommendations for Permanent Pacing for Acquired Atrioventricular (AV) Block in Adults

Class I

1. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level associated with bradycardia with symptoms (including heart failure) or ventricular arrhythmias presumed to be due to AV block. (Level of evidence: C)
2. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level associated with arrhythmias and other medical conditions that require drug therapy that results in symptomatic bradycardia. (Level of evidence: C)
3. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level in awake, symptom-free patients in sinus rhythm, with documented periods of asystole 3.0 seconds or longer or any escape rate less than 40 beats/min, or with an escape rhythm that is below the AV node. (Level of evidence: C)
4. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level in awake, symptom-free patients with atrial fibrillation and bradycardia with 1 or more pauses of at least 5 seconds or longer. (Level of evidence: C)
5. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level after catheter ablation of the AV junction. (Level of evidence: C)
6. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level associated with postoperative AV block that is not expected to resolve after cardiac surgery. (Level of evidence: C)
7. Permanent pacemaker implantation is indicated for third-degree and advanced second-degree AV block at any anatomic level associated with neuromuscular diseases with AV block, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy, with or without symptoms. (Level of evidence: B)
8. Permanent pacemaker implantation is indicated for second-degree AV block with associated symptomatic bradycardia regardless of type or site of block. (Level of evidence: B)
9. Permanent pacemaker implantation is indicated for asymptomatic persistent third-degree AV block at any anatomic site with average awake ventricular rates of 40 beats/min or faster if cardiomegaly or LV dysfunction is present or if the site of block is below the AV node. (Level of evidence: B)
10. Permanent pacemaker implantation is indicated for second- or third-degree AV block during exercise in the absence of myocardial ischemia. (Level of evidence: C)

Class IIa

1. Permanent pacemaker implantation is reasonable for persistent third-degree AV block with an escape rate greater than 40 beats/min in asymptomatic adult patients without cardiomegaly. (Level of evidence: C)
2. Permanent pacemaker implantation is reasonable for asymptomatic second-degree AV block at intra- or infra-His levels found at electrophysiologic study. (Level of evidence: B)
3. Permanent pacemaker implantation is reasonable for first- or second-degree AV block with symptoms similar to those of pacemaker syndrome or hemodynamic compromise. (Level of evidence: B)
4. Permanent pacemaker implantation is reasonable for asymptomatic type II second-degree AV block with a narrow QRS complex. When type II second-degree AV block occurs with a wide QRS, including isolated right bundle branch block, pacing becomes a class I recommendation. (Level of evidence: B)

Class IIb

1. Permanent pacemaker implantation may be considered for neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with any degree of AV block (including first-degree AV block), with or without symptoms, because there may be unpredictable progression of AV conduction disease. (Level of evidence: B)
2. Permanent pacemaker implantation may be considered for AV block in the setting of drug use or drug toxicity when the block is expected to recur even after the drug is withdrawn. (Level of evidence: B)

Class III

1. Permanent pacemaker implantation is not indicated for asymptomatic first-degree AV block. (Level of evidence: B)
2. Permanent pacemaker implantation is not indicated for asymptomatic type I second-degree AV block at the supra-His (AV node) level or that not known to be intra- or infra-His. (Level of evidence: C)
3. Permanent pacemaker implantation is not indicated for AV block that is expected to resolve and is unlikely to recur (e.g., drug toxicity, Lyme disease, or transient increases in vagal tone or during hypoxia in sleep apnea syndrome in the absence of symptoms). (Level of evidence: B)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices); American Association for Thoracic Surgery; Society of Thoracic Surgeons. ACC/AHA/HRS 2008 Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2008;117:e350-408.

Box 5.3 Recommendations for Permanent Pacing in Chronic Bifascicular Block

Class I

1. Permanent pacemaker implantation is indicated for advanced second-degree AV block or intermittent third-degree AV block. (Level of evidence: B)
2. Permanent pacemaker implantation is indicated for type II second-degree AV block. (Level of evidence: B)
3. Permanent pacemaker implantation is indicated for alternating bundle branch block. (Level of evidence: C)

Class IIa

1. Permanent pacemaker implantation is reasonable for syncope not demonstrated to be due to AV block when other likely causes have been excluded, specifically ventricular tachycardia (VT). (Level of evidence: B)
2. Permanent pacemaker implantation is reasonable for an incidental finding at electrophysiologic study of a markedly prolonged HV (from the bundle of His to the ventricles) interval (100 ms or greater) in asymptomatic patients. (Level of evidence: B)
3. Permanent pacemaker implantation is reasonable for an incidental finding at electrophysiologic study of pacing-induced infra-His block that is not physiologic. (Level of evidence: B)

Class IIb

1. Permanent pacemaker implantation may be considered in the setting of neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with bifascicular block or any fascicular block, with or without symptoms. (Level of evidence: C)

Class III

1. Permanent pacemaker implantation is not indicated for fascicular block without AV block or symptoms. (Level of evidence: B)
2. Permanent pacemaker implantation is not indicated for fascicular block with first-degree AV block without symptoms. (Level of evidence: B)

AV, atrioventricular.

From Antman EM, Anbe DT, Armstrong PW, et al: ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction—Executive summary: A report of the American College of Cardiology/American Heart Association task force on practice guidelines (writing committee to revise the 1999 guidelines for the management of patients with acute myocardial infarction). *Circulation* 2004;110:588-636.

Box 5.4 Recommendations for Permanent Pacing for Atrioventricular (AV) Block Associated with Acute Myocardial Infarction

Class I

1. Permanent ventricular pacing is indicated for persistent second degree AV block in the His-Purkinje system with alternating bundle branch block or third-degree AV block within or below the His-Purkinje system after ST-segment elevation myocardial infarction. (Level of evidence: B)
2. Permanent ventricular pacing is indicated for transient advanced second- or third-degree infranodal AV block and associated bundle branch block. If the site of block is uncertain, an electrophysiologic study may be necessary. (Level of evidence: B)
3. Permanent ventricular pacing is indicated for persistent and symptomatic second- or third-degree AV block. (Level of evidence: C)

Class IIb

1. Permanent ventricular pacing may be considered for persistent second- or third-degree AV block at the AV node level, even in the absence of symptoms. (Level of evidence: B)

Class III

1. Permanent ventricular pacing is not indicated for transient AV block in the absence of intraventricular conduction defects. (Level of evidence: B)
2. Permanent ventricular pacing is not indicated for transient AV block in the presence of isolated left anterior fascicular block. (Level of evidence: B)
3. Permanent ventricular pacing is not indicated for new bundle branch block or fascicular block in the absence of AV block. (Level of evidence: B)
4. Permanent ventricular pacing is not indicated for persistent asymptomatic first-degree AV block in the presence of bundle branch or fascicular block. (Level of evidence: B)

From Epstein AE, DiMarco JP, Ellenbogen KA, et al: American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices); American Association for Thoracic Surgery; Society of Thoracic Surgeons. ACC/AHA/HRS 2008 Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2008;117:e350-408.

QT syndrome (class IIb indication, level of evidence B).¹ Atrial-based pacing (“AAI” or “DDD” mode) is considered the preferred pacing mode for prevention of polymorphic ventricular tachycardia associated with the congenital long QT syndrome. Pacing the left ventricle can improve hemodynamics in patients with dilated cardiomyopathy and bundle branch block by altering the activation sequence and influencing regional contractility, and is particularly effective in patients with left bundle branch block. This is referred to as “biventricular pacing” or “cardiac

resynchronization therapy” and is beyond the scope of this chapter.

INDICATIONS FOR TEMPORARY PACING

Temporary pacing is typically reserved for situations in which an electrical disturbance is transient or reversible—for example, Lyme carditis, drug overdose, or inferior wall infarction—or when there is an ongoing contraindication

Figure 5.1 Telemetry strip demonstrating antitachycardia pacing. Pacing is delivered at a rate that is slightly faster than the underlying ventricular tachycardia, ultimately terminating the arrhythmia.

Figure 5.2 Telemetry strip demonstrating torsades de pointes. The rhythm is sinus with both conducted (green stars) and nonconducted (red stars) P waves. Premature ventricular complexes emerge from a dramatically prolonged QT-U complex (black arrow), eventually initiating polymorphic ventricular tachycardia.

to the implantation of a permanent device, most often because of infection.

ATRIOVENTRICULAR NODAL DYSFUNCTION

The “level” of AV block—whether at the level of the AV node or below the AV node in the His-Purkinje conduction system—is critical in determining the need for temporary pacing. AV nodal block improves with measures that accelerate AV nodal conduction, like atropine, dopamine, and isoproterenol. Infranodal block—that is, block below the level of the AV node at the bundle of His or bundle branches—may paradoxically worsen with these agents owing to downstream block in an already diseased His-Purkinje system. The origin of the escape rhythm—whether “proximal” or “distal” in the cardiac conduction system—predicts both its rate and stability. Complete heart block at the level of the AV node is associated with an escape rhythm arising from the AV junction, His bundle, or proximal fascicles; a narrow QRS morphologic pattern; and a heart rate in excess of 60 beats per minute. Infranodal block is associated with an escape rhythm arising from the bundle branches or even ventricular myocardium, a wide and often bizarre QRS morphologic pattern, and a heart rate in the range of 40 beats per minute.¹⁰ Complete heart block with a junctional escape rhythm does not typically require temporary pacing, unless accompanied by hypotension. In contrast, complete heart block with a ventricular escape rhythm is inherently unstable and usually requires temporary pacing, even if hemodynamically stable. History can be quite helpful in risk stratification. A history of syncope in a patient who presents with advanced second-degree AV block may portend a higher degree of AV block or pause-dependent torsades de pointes, and there should be a very low threshold for temporary pacing.¹¹

HIGH-GRADE AND PAROXYSMAL ATRIOVENTRICULAR BLOCK

In the critical care setting, it is crucial to distinguish between paroxysmal and vagally mediated AV block. Vagally mediated AV block due to *extrinsic*, parasympathetic input is characterized by progressive sinus slowing, progressive PR prolongation, Mobitz type I second-degree AV block immediately before the onset of complete heart block, and sinus slowing during the episode (Fig. 5.3). In contrast, high-grade AV block due to an *intrinsic* failure of a diseased His-Purkinje system—also termed “paroxysmal” AV block—is characterized by a constant sinus rate, or even sinus acceleration during the episode (Fig. 5.4). Patients with paroxysmal AV block *usually* have some sort of baseline conduction abnormality on their surface 12-lead electrocardiogram—most commonly, right bundle branch block—but this finding is not absolute. The hallmark of paroxysmal AV block is *immediate* transition from apparently normal conduction to complete AV block and ventricular asystole. This is usually triggered by a pause after a premature atrial or ventricular depolarization, but vagally mediated sinus slowing can have the same effect, complicating the interpretation of these events. Vagally mediated heart block is typically benign, is atropine responsive, and does *not* require temporary pacing. Paroxysmal AV block can be fatal and requires temporary transvenous pacing until a permanent pacemaker can be placed.¹²

ELECTROLYTE AND METABOLIC DERANGEMENT

Hyperkalemia can precipitate complete AV block and can also elevate pacing thresholds in permanent pacemaker systems.¹³⁻¹⁵ A progressive increase in extracellular potassium raises the resting membrane potential, inactivating

Figure 5.3 Telemetry strip demonstrating vagally mediated complete heart block. There is progressive PR prolongation (*black boxes*) and sinus slowing (*red stars*) just before the development of complete heart block, reflecting parasympathetic innervation of both the sinus and atrioventricular nodes.

Figure 5.4 Telemetry strip demonstrating paroxysmal atrioventricular (AV) block. There is a brief sinus pause (*horizontal black arrow*) followed by multiple, nonconducted P waves (*red stars*) with associated sinus acceleration, reflecting an intrinsic failure of AV nodal conduction. The nearly 7-second pause is eventually interrupted by a junctional escape complex (*vertical black arrow*).

voltage-gated sodium channels that depend upon a sufficiently negative resting membrane potential for normal function. The effect is more pronounced in the atrium and ventricle than the cells of the specialized conduction system, explaining why the characteristic changes in the P wave and QRS complex typically precede sinoatrial (SA) and AV nodal dysfunction: “peaked” T waves and QT shortening (potassium level 5.5 mEq/L); PR prolongation and QRS widening (potassium level 6.5 mEq/L); a “sinoventricular” rhythm, due to the apparent absence of atrial activity (potassium level 8-9 mEq/L); and lastly, a “sine wave” pattern due to merging of the QRS and T wave that predicts impending cardiac arrest (potassium level 10 mEq/L).¹⁶ Nevertheless, the 12-lead electrocardiogram may be entirely normal in cases of pronounced hyperkalemia, and AV block may occur in isolation.¹⁷⁻²⁰ Therefore, a routine metabolic evaluation is indicated in all patients with new conduction deficits.

The initial management of hyperkalemia-induced heart block is medical. If 12-lead electrocardiographic findings are pathognomonic for hyperkalemia, empiric treatment is appropriate while laboratory studies are pending. The administration of calcium chloride or calcium gluconate acutely antagonizes the electrical effects of potassium, partially restoring normal SA automaticity and conduction velocity. The effect is short-lived, however, and does nothing to correct extracellular potassium levels. Insulin, albuterol, and other catecholamines reduce extracellular potassium through activation of the Na^+/K^+ -ATPase pump, and sodium polystyrene sulfonate (Kayexalate) facilitates its

gastrointestinal excretion. Dialysis is the most definitive treatment but requires peritoneal or vascular access. Temporary pacing may be helpful, but prohibitively high capture thresholds may be problematic. In patients with a preexisting cardiac device, pacing outputs can be increased if there is intermittent “failure to capture,” but the underlying metabolic disturbance takes precedence.

Case reports and animal studies suggest a link between metabolic acidosis and heart block, and metabolic acidosis frequently accompanies hyperkalemia in the setting of chronic kidney disease.²¹ The administration of sodium bicarbonate acutely raises extracellular pH and indirectly lowers extracellular potassium, and may improve responsiveness to vasopressors in emergent situations.²²

Hyponatremia, hypokalemia, hypomagnesemia, and hypocalcemia have not been implicated in heart block.

DRUG SIDE EFFECTS

A number of drugs can cause severe sinus bradycardia, AV block, or both. β -Adrenergic blockers and calcium channel blockers are both negatively chronotropic and inotropic, and their administration can result in significant bradycardia and hypotension, particularly in overdose. Digoxin toxicity may present with high-grade or complete AV block, further compounded by atrial or ventricular tachycardia due to increased automaticity. Amiodarone, dronedarone, and sotalol—class III antiarrhythmic drugs with mixed antiarrhythmic effects—frequently cause bradycardia due to SA

or AV conduction defects. Some studies suggest that drug-induced AV block—particularly at therapeutic levels—is a predictor of future conduction disorders.²³

Clearly, the initial treatment is discontinuation of the offending drug(s). Directed therapy may occasionally be useful as well, but the evidence is largely anecdotal. β -Adrenergic blocker toxicity may respond to glucagon, and calcium channel blocker toxicity may respond to calcium or glucagon in refractory cases.²⁴⁻²⁸ Vasopressors are occasionally necessary because of the vasodilatory and negative inotropic effects of these drugs. Digoxin toxicity can be treated with digoxin antibody fragments (Digibind).²⁹ If hemodynamic instability persists in the setting of severe bradycardia, temporary pacing is indicated. β -Adrenergic blockers and calcium channel blockers increase pacing thresholds in permanent devices; if failure to capture is noted in a patient with suspected overdose of these agents, a temporary increase in pacing output may solve the problem.³⁰

INFECTIOUS DISEASE

Lyme disease is the most common tick-borne illness in North America.³¹ Erythema migrans is sufficient for diagnosis, but most patients cannot recall a tick exposure or rash.³² The diagnosis of Lyme carditis requires serologic testing for confirmation, and *Borrelia burgdorferi* IgM and IgG antibodies are positive in the vast majority of patients with the disease.³³ Regardless of patient history, the diagnosis of Lyme carditis should always be entertained in a patient presenting with heart block in an endemic area. Typically, Lyme carditis affects the AV node and is associated with a stable, junctional escape rhythm, but more diffuse involvement of the His-Purkinje system with a slower, more unstable escape is also possible.³⁴ Although conduction deficits regress rapidly and completely with appropriate antibiotic therapy, temporary pacing is occasionally necessary.

Infective endocarditis can be complicated by a broad spectrum of conduction disturbances, including first-degree AV delay, bundle branch block, and complete heart block. Any new conduction deficit suggests perivalvular abscess, due to the proximity of the compact AV node and bundle branches to the membranous septum.^{35,36} Conduction disturbances most commonly complicate aortic valve endocarditis, but the tricuspid valve and mitral valve are also susceptible.³⁷⁻³⁹ Perivalvular abscess and heart block are indications for surgical repair.⁴⁰ Serial 12-lead electrocardiography should be performed in all patients with endocarditis, and temporary pacing should be strongly considered for any progressive conduction disturbance.

Lymphocytic and giant cell myocarditis are typically associated with acute systolic dysfunction, but they can also be complicated by severe electrical abnormalities, including complete heart block. Lymphocytic myocarditis carries a more favorable prognosis than giant cell myocarditis, but permanent pacemaker dependency is possible with either condition.⁴¹

AFTER MYOCARDIAL INFARCTION

Official guidelines for temporary and permanent pacing after ST-segment elevation myocardial infarction were last updated in 2004, and permanent pacemaker indications

following myocardial infarction were updated in 2008 as previously discussed.^{1,42} Recommendations for temporary pacing are largely based on expert opinion, in addition to case reports, case series, and published summaries from before the reperfusion era.

The need for temporary pacing is frequently made at the time of percutaneous intervention by the interventional cardiologist, but familiarity with official guidelines and an understanding of the risk of progression is critical in the appropriate management of the patient after myocardial infarction. Clearly, myocardial infarction complicated by asystolic arrest and symptomatic bradycardia justifies temporary transvenous pacing. Temporary transvenous pacing is recommended when an ST-segment elevation myocardial infarction is complicated by new bifascicular block or complete bundle branch block and concomitant Mobitz type II second-degree AV block, regardless of the culprit artery. It is also recommended for alternating bundle branch block, regardless of the status of AV conduction. Alternating bundle branch block—right bundle branch block alternating with left bundle branch block, or bifascicular block with right bundle branch block and alternating left anterior and posterior fascicular block—is a marker of severe His-Purkinje disease. In particular, bifascicular block with right bundle branch block and left posterior fascicular block carries a very poor prognosis with a high risk of progression to complete heart block (Fig. 5.5A and B).⁴³ In cases of Mobitz type II second-degree AV block with normal intraventricular conduction, fascicular block, and old bundle branch block, transvenous pacing is given a less stringent recommendation. Temporary transcutaneous pacing is recommended in every other scenario, with the exception of normal AV nodal and intraventricular conduction, isolated first-degree AV block, isolated left anterior or posterior fascicular block, and isolated old bundle branch block (Table 5.1).

The culprit artery has prognostic implications. Complete heart block complicating anterior wall myocardial infarction—usually involving the proximal left anterior descending artery—is due to necrosis of the interventricular septum and irreversible damage to the His-Purkinje conduction system. In contrast, complete heart block in inferior wall infarction—usually involving the proximal right coronary artery (RCA)—is vagally mediated and atropine sensitive in the first hours of infarction.⁴⁴ Local accumulation of adenosine in the days after infarction may lead to persistent, atropine-insensitive AV block, but permanent pacing is rarely indicated.⁴⁵ Because the RCA supplies the SA nodal artery in 90% of cases, a proximal RCA infarction may also be complicated by sinus bradycardia, SA exit block, and sinus arrest; these, too, are typically transient in nature and atropine responsive.

TORSADES DE POINTES

Torsades de pointes is a polymorphic (or “twisting” around the baseline) ventricular arrhythmia associated with QT prolongation. Because the QT interval is directly proportional to heart rate—that is, the QT interval lengthens at slow heart rates and shortens at fast heart rates—torsades de pointes is usually a self-terminating and recurrent arrhythmia. It can rarely degenerate into ventricular fibrillation

Figure 5.5 Bifascicular block following acute, left anterior descending coronary artery infarction. **A**, A 12-lead electrocardiogram demonstrating sinus rhythm with normal atrioventricular (AV) nodal conduction, but right bundle branch block and left posterior fascicular block. There are also pathologic Q waves in leads V₁ to V₄, consistent with an anterior wall infarction due to occlusion of a proximal left anterior descending artery. **B**, A 12-lead electrocardiogram of the same patient, 1 week later. There is now high-grade AV block with a right bundle branch block and left anterior fascicular block, due to necrosis of the His-Purkinje system that has left only the left posterior fascicle capable of conduction.

and require external defibrillation, but this development is uncommon. The underlying QT prolongation can be either congenital or acquired, the latter of which is by far more common in the critical care setting and most often is due to administration of a culprit drug or severe electrolyte disturbance.

The most important considerations in the management of torsades de pointes are appropriate recognition of the problem, correction of the underlying cause(s), and avoidance of QT-prolonging drugs that can further exacerbate the problem. Although this arrhythmia is polymorphic by definition, not all polymorphic ventricular arrhythmias are due to torsades de pointes. Polymorphic ventricular tachycardia may complicate acute coronary syndrome, but it is typically associated with a suggestive clinical history and ST-segment deviation. Temporary or permanent pacemaker malfunction with ventricular undersensing can lead to “R on T” pacing, and certain pacemaker settings that minimize ventricular pacing can predispose to “long-short”

sequences and polymorphic ventricular arrhythmias as well.⁴⁶⁻⁴⁹ If ventricular tachycardia is reliably initiated with pacing, pacemaker reprogramming may resolve the problem; electrophysiology consultation should be sought immediately.

The administration of magnesium sulfate (1-2 g over 5-10 minutes) is acutely effective in most patients.⁵⁰ If ineffective, isoproterenol (1-4 µg/minute) can accelerate the heart rate and thereby shorten the QT, but this should be avoided in long QT syndrome—particularly long QT type 1—because of the potential for proarrhythmia.

Temporary pacing is indicated in patients who fail electrolyte supplementation and pharmacologic augmentation of the heart rate, or patients with severe AV conduction disturbances. Temporary pacing shortens the action potential and QT interval but also truncates the progressive, post-PVC (premature ventricular contraction) pauses that typically trigger an episode (see Fig. 5.2).⁵¹ Typically, pacing at a rate of 90 to 100 beats per minute is sufficient to

Table 5.1 Recommendations for Treatment of Atrioventricular and Intraventricular Conduction Disturbances During STEMI

LAFB indicates left anterior fascicular block; LPFB, left posterior fascicular block; RBBB, right bundle-branch block; A, atropine; TC, transcutaneous pacing; TV, temporary transvenous pacing; STEMI, ST elevation myocardial infarction; AV, atrioventricular; and MI, myocardial infarction.

Four possible actions, or therapeutic options, are listed and classified for each bradyarrhythmia or conduction problem:

1. Observe: continued ECG monitoring, no further action planned.
2. A, and A*: atropine administered at 0.6 to 1.0 mg IV every 5 minutes to up to 0.04 mg/kg. In general, because the increase in sinus rate with atropine is unpredictable, this is to be avoided unless there is symptomatic bradycardia that will likely respond to a vagolytic agent, such as sinus bradycardia or Mobitz I, as denoted by the asterisk above.
3. TC: application of transcutaneous pads and standby transcutaneous pacing with no further progression to transvenous pacing imminently planned.
4. TV: temporary transvenous pacing. It is assumed, but not specified in the table, that at the discretion of the clinician, transcutaneous pads will be applied and standby transcutaneous pacing will be in effect as the patient is transferred to the fluoroscopy unit for temporary transvenous pacing.

From Epstein et al: Circulation 2008;117:e350-408.

suppress ventricular ectopy, but rates as fast as 140 beats per minute may be necessary.⁵² Patients with preexisting cardiac devices can be adjusted at the bedside to achieve the same effect. In patients with normal AV nodal conduction, atrial pacing is preferred.

CONDITIONS THAT DO NOT NORMALLY REQUIRE PACING

HYPOTHERMIA

Hypothermia can produce dramatic electrocardiographic abnormalities—PR prolongation, QRS widening, and QT prolongation, in addition to both atrial and ventricular arrhythmias—and familiarity with this condition is increasingly important in the critical care setting owing to the widespread adoption of therapeutic hypothermia in survivors of cardiac arrest.^{53,54} Moderate (32° C to 33.9° C) hypothermia causes a reduction in cardiac output that is mediated by sinus bradycardia, but this is accompanied by an increase in myocardial contractility and proportional decrease in basal metabolism. No specific treatment is needed, and attempts to increase the heart rate with drug or temporary pacing are counterproductive.⁵⁵ Deep hypothermia (<30° C) is associated with increased risk of atrial and ventricular arrhythmias, reduced responsiveness to electrical and pharmacologic cardioversion, and increased sensitivity to mechanical manipulation.⁵⁶ One case report describes the successful resuscitation of two severely hypothermic patients with transcutaneous pacing,⁵⁷ and another describes the near immediate initiation of ventricular fibrillation with transvenous pacing.⁵⁸ The role of temporary pacing—whether transcutaneous or transvenous—is limited, and should be reserved for extreme situations of hemodynamic and electrical instability. The primary treatment is rewarming.

HYPOTHYROIDISM

Severe hypothyroidism is most commonly seen in the elderly and is most often precipitated by infections. Case reports have established that severe hypothyroidism and myxedema coma can cause a range of AV conduction abnormalities, including complete heart block. The symptoms of hypothyroidism can be vague, and the electrocardiographic manifestations—P wave flattening, low QRS voltage and intraventricular conduction delays, QT prolongation, and T wave flattening or inversion—are nonspecific. Thyroid hormone replacement can quickly normalize conduction but may take up to several weeks in some patients.⁵⁹⁻⁶¹ Patients who present with new conduction abnormalities—particularly the elderly and infirm—should be routinely screened for hypothyroidism. Temporary pacing may be needed in cases of advanced AV block, but thyroid hormone supplementation is usually curative.

OBSTRUCTIVE SLEEP APNEA

Obstructive sleep apnea has been associated with cyclic patterns of SA and AV nodal conduction disturbances, occasionally resulting in prolonged periods of asystole during

sleep.⁶² In general, nocturnal arrhythmias are less clinically relevant than those during the day, and the need for intervention should be taken in the context of the clinical situation. Atropine has been shown to abolish cyclic variation and nocturnal bradycardia, suggesting that autonomic influences play a role.⁶³ One study suggested that atrial overdrive pacing reduces the number of central and obstructive apneic episodes,⁶⁴ but subsequent studies have shown no benefit and pacing does *not* have a role in the chronic management of this disorder.⁶⁵⁻⁶⁷ Continuous positive airway pressure abolishes conduction disturbances in the majority of patients, suggesting that hypoxia plays a role in the pathophysiology of the condition. It is the therapy of choice.⁶⁸

PREOPERATIVE ANESTHESIA

Preexisting His-Purkinje disease—complete right or left bundle branch block, or bifascicular block, for example—does *not* routinely require temporary pacing before surgery. Patients with complete heart block with junctional, and particularly ventricular escape complexes, should be considered for temporary pacing due to the potentially suppressive effects of general anesthesia. Patients with underlying left bundle branch block who require Swan-Ganz catheterization have a small risk of procedurally related complete heart block due to catheter-induced right bundle branch block.⁶⁹ In these situations, right-sided heart catheterization should be performed under fluoroscopy, and transcutaneous pacing should be immediately available. The presence of an “rS” complex in lead V₁ may reflect left-to-right septal activation and left bundle branch *delay*, rather than complete left bundle branch block; the risk of catheter-induced heart block may be lower in these circumstances.⁷⁰

SEIZURE

Severe sinus bradycardia and prolonged periods of asystole complicate less than 0.4% of seizures.⁷¹ “Ictal bradycardia” is felt to be vagally mediated, but there is disagreement in the epilepsy community about its potential contribution to sudden death.^{72,73} Although the majority of episodes terminate spontaneously, some patients are ultimately referred for pacemaker implantation. In the critical care setting, continuous electrocardiographic and encephalographic monitoring can be quite helpful if clinical features suggest prodromal seizure activity. The most appropriate management—including the potential need for temporary pacing—is unclear.

SPINAL CORD INJURY AND TRACHEAL SUCTIONING

Severe cervical injury is nearly universally associated with sinus bradycardia, sinus pauses, and hypotension in the days after injury, but these changes typically resolve within 2 to 6 weeks.⁷⁴ Endotracheal intubation, tracheal suctioning, and repositioning can precipitate prolonged, vagally mediated pauses in these patients, presumably due to impairment of the sympathetic nervous system input during periods of increased parasympathetic tone. There have been case reports of asystolic cardiac arrest during tracheal suctioning, but supplemental oxygen therapy was at least

partially effective in preventing further episodes, suggesting that hypoxia played a role.⁷⁵ The administration of atropine, theophylline, aminophylline, and isoproterenol—individually, or in combination—may attenuate these pauses, but their administration may be ineffective in the short-term and cumbersome in the long-term. There is no consensus on the issue, but some authors advocate placement of a permanent pacemaker in patients with a prolonged requirement of mechanical ventilation, due to the unpredictable nature of these events.⁷⁶ Temporary pacing can be considered on a case-by-case basis, but it is important to recognize that the primary underlying problem is autonomic in nature.

ESOPHAGEAL AND TRANSTHORACIC PACING

For reasons of efficacy and patient comfort, esophageal pacing has fallen out of favor in the last 2 decades in favor of transcutaneous and transvenous pacing techniques. Transthoracic pacing with direct, percutaneous placement of a needle into the heart is obsolete.

The esophagus lies immediately posterior to the left atrium, and an esophageal pill electrode was historically used to record atrial activity. Esophageal recording makes it very easy to identify atrial activity, which can be useful in the differentiation of ventricular tachycardia and supraventricular tachycardia with aberrant conduction.⁷⁷ The presence of AV dissociation is virtually pathognomonic for ventricular tachycardia, but atrial activity is often difficult to recognize

on the 12-lead electrocardiogram, particularly with fast, wide complex arrhythmias. Nevertheless, there are easy-to-use algorithms that allow for the rapid and relatively accurate diagnosis of wide complex rhythms, often regardless of whether atrial activity is apparent on the 12-lead electrocardiogram.^{78,79}

TRANSCUTANEOUS PACING

BACKGROUND

First described by Zoll in 1952 in the management of Stokes-Adams attacks, transcutaneous pacing involves the delivery of pacing stimuli through cutaneous patch electrodes.⁸⁰ It is the fastest and technically least challenging means of temporary pacing, and it does not introduce the risks associated with vascular access and transvenous pacing. The initial system required the subcutaneous insertion of 21-gauge needles and was limited by high pacing thresholds and significant pain. The technology has evolved over time, but these issues remain to some degree. Capture is still unsuccessful in a significant minority of patients, and it can be difficult to assess capture because of saturation artifact from pacing stimuli—particularly if pacing outputs are high (Fig. 5.6).⁸¹ Transcutaneous pacing is still painful and generally requires the administration of sedation or analgesics. It is best tolerated in deeply anesthetized or unconscious patients, and most appropriate in situations in which pacing is required only briefly or intermittently, or as a bridging measure for placement of a transvenous system.

Figure 5.6 Telemetry strip demonstrating ineffective transcutaneous pacing. There is an underlying junctional rhythm (red stars) that “marches through” the pacing artifact without any change in rate or rhythm, proving that transcutaneous pacing fails to capture the myocardium. The pacing artifact saturates the tracing and makes interpretation quite difficult.

METHODS

Commercially available external defibrillators have both pacing *and* defibrillating capability. The skin should be cleaned thoroughly with alcohol, but preferably not shaved, because the pain associated with pacing is typically localized to small abrasions and local salt deposits on the skin.⁸² The patch electrodes should be arranged in an anteroposterior position with one patch over the mid-dorsal spine at the left paravertebral position, and the other over the point of maximal impulse. If abrasions are present, the patches can be positioned in an adjacent area with intact skin. The external generator should be turned on at the lowest pacing output, and then increased in a step-wise fashion until reliable capture is observed on telemetry. It can be difficult to distinguish pacing artifact from capture, but the presence of a QRS complex and T wave—which represents cardiac depolarization and repolarization—is confirmatory. Capture should also be confirmed by the presence of a palpable or measurable pulse that matches the paced rate. The pacing outputs should be set *just above* capture threshold to minimize pacing artifact, pain, and risk of proarrhythmia.

Capture thresholds are predictably higher than with endocardial pacing, but most patients will capture at a pacing output of 40 to 70 mA. The capture threshold is proportional to the size of the patch electrode because of a reduction in current density—that is, larger electrodes require higher output for capture.⁸³ Higher impedance electrodes are preferred for pacing, but standard patch electrodes are more practical in daily practice. Hypoxia, acidosis, and prolonged periods of asystole may increase the pacing threshold.⁸⁴

The pacing rate is dictated by the underlying rhythm and clinical indication. A patient with complete heart block and hemodynamic instability should be paced at 60 to 90 beats per minute, until transvenous pacing can be established. A patient with prolonged postconversion pauses or only intermittent heart block should be paced at 40 beats per minute to minimize pacing.

EPICARDIAL PACING

BACKGROUND

Permanent pacing is required in roughly 2% of coronary artery bypass grafting and up to 7.7% of valve surgery cases,⁸⁵⁻⁸⁷ but transient SND, fascicular block, bundle branch block, and AV block are common within the first few days following surgery.⁸⁸ Epicardial pacing offers a safe and well-tolerated “bridge” to recovery, avoiding the need for transcutaneous and transvenous pacing. It also allows for prevention, diagnosis, and management of postoperative atrial arrhythmias, and the optimization of hemodynamics in the critical care setting.

METHODS

Epicardial wires are typically placed on the anterior right atrium and right ventricle at the conclusion of open heart surgery, then threaded through the right and left subcostal

areas for attachment to an external pulse generator. Most surgeons will routinely implant both atrial and ventricular leads because AV synchrony and native conduction is preferred whenever possible, particularly in patients with pre-existing systolic dysfunction.^{89,90}

Pacing and sensing thresholds typically deteriorate rapidly over 3 to 5 days owing to local inflammation, and should be checked on a daily basis to ensure adequate safety margins, particularly in patients with ongoing pacemaker dependency. External pulse generators can deliver impulses up to 20 mA, but high outputs may only further exacerbate the local inflammation that produces high pacing thresholds.⁹¹ Alternate locations—including the basal and lateral left ventricle—may be associated with more favorable pacing thresholds and cardiac performance.⁹²

PREVENTION OF ATRIAL ARRHYTHMIAS

Atrial fibrillation complicates 20% to 50% of cardiac surgery cases, resulting in longer times in the hospital, increased hospital costs, and higher morbidity and mortality rates.⁹³ The administration of β -adrenergic blockers and amiodarone constitutes first-line therapy, but there is some data to support the use of atrial pacing in the postoperative setting.^{94,95} One small, prospective study demonstrated a 17% absolute risk reduction of postoperative atrial fibrillation through the use of “overdrive” atrial pacing (AAI mode at a minimum of 80 beats per minute) for 24 hours on the second postoperative day, but longer-term follow-up was not reported in the study.⁹⁶ The trials have been small and heterogeneous in design, but meta-analysis suggests an absolute reduction of 10% of postoperative atrial fibrillation with overdrive atrial pacing.⁹⁷

TREATMENT OF ATRIAL ARRHYTHMIAS

Rapid, “burst” atrial pacing can be easily performed at the bedside using a standard, external pulse generator. Typical atrial flutter and other macro-reentrant arrhythmias that involve the right atrium are often susceptible to pace termination, due to depolarization of the “excitable gap” of the circuit. Pace termination is simply performed by pacing the atrium at a sufficiently high pacing output to guarantee atrial capture at a rate that is slightly faster than the arrhythmia. One can start pacing at 10 mA and 10 to 20 beats per minute faster than the atrial rate for 5 to 10 seconds, but any of these parameters can be adjusted if initial attempts are unsuccessful. Because rapid ventricular pacing can easily precipitate ventricular fibrillation, it is essential to confirm the epicardial system is connected appropriately before any pacing attempt. Burst pacing may cause atrial flutter to degenerate into atrial fibrillation, which is often associated with a slower, better-tolerated heart rate.

DIAGNOSIS OF WIDE COMPLEX ARRHYTHMIAS

Atrial activity can be directly recorded by connecting the pin of the atrial wire to precordial lead V₁ of the 12-lead electrocardiogram, elucidating the mechanism of a tachycardia (Fig. 5.7).

RISKS

Some centers argue against the routine placement of epicardial wires because of their cost and potential risk, but their use remains nearly ubiquitous. The frequency of complications is far less than 1%, but case reports have described the inadvertent laceration of saphenous vein grafts,^{98,99} right

atrium,¹⁰⁰ and right ventricular outflow tract¹⁰¹ with development of either pericardial tamponade or hemothorax following their removal, and infection attributed to abandonment and bacterial colonization of the wires.^{102,103} Epicardial wires are almost always removed with gentle traction, and the prevailing thought is that their occasional abandonment does not constitute a risk to the patient. To minimize risk, they should be pulled after discontinuation of anticoagulation therapy in a monitored setting.

Figure 5.7 Temporary atrial pacing wires utilized for arrhythmia diagnosis. Epicardial pacing wires can be utilized for arrhythmia diagnosis in postoperative coronary artery bypass graft patients when P waves cannot be clearly visualized on surface electrocardiography. One of the epicardial atrial wires is clipped to lead V₁ on the standard electrocardiogram machine. The unipolar atrial electrogram now appears on lead V₁ referenced to surface lead V₅ in this figure, demonstrating two P waves for every QRS complex, making the diagnosis of atrial flutter.

TRANSVENOUS PACING

BACKGROUND

Cardiac pacing with an endocardial electrode was first introduced in 1959 and quickly supplanted transcutaneous pacing as the method of choice for temporary pacing.¹⁰⁴ Transvenous pacing is more reliable and more comfortable than transcutaneous pacing, but it also takes longer to initiate and introduces some degree of procedural risk.

METHODS

The internal jugular, subclavian, or femoral vein can be used, but the internal jugular is generally the preferred approach. The subclavian vein should be preserved for a permanent device, and the femoral vein carries a higher risk of infection, impedes patient movement, and requires fluoroscopic guidance. A variety of catheters are commercially available, the selection of which depends on operator preference, patient characteristics, and the availability of fluoroscopy (Fig. 5.8). Fluoroscopic imaging should be used routinely in patients with significant tricuspid regurgitation owing to the potential difficulty of catheter advancement across the tricuspid annulus in this setting. Fluoroscopic guidance should also be considered in patients with preexisting left bundle branch block and intermittent heart

Figure 5.8 Temporary bipolar pacing catheters. From left to right, atrial J, semifloating balloon-tipped, and two ventricular catheters with different curves. (Courtesy of Daig Corporation/St. Jude Medical, Minneapolis, MN.)

block due to the potential for catheter-induced complete heart block.

Fluoroscopy simplifies catheter placement, but it may be unavailable, or a patient may simply be too unstable to transport to the catheterization laboratory in the critical care setting. If portable fluoroscopy is unavailable, the procedure is best performed “blindly” at the bedside using a “floppy,” balloon-tipped catheter. Placement can be facilitated by electrocardiographic guidance, with or without pacing. If positioning is performed *with* pacing, the pacing catheter should be attached to an external pulse generator and set to pace at a rate slightly faster than the patient’s intrinsic rate and at an intermediate pacing output (5 mA) to ensure capture. Catheter contact and position can be assessed by examination of the paced QRS morphologic appearance: an “LBBB” morphologic pattern with positive QRS complexes in leads II, III, and aVF (inferior frontal axis) suggests catheter position in the right ventricular outflow tract (Fig. 5.9) whereas an “LBBB” morphologic pattern with negative QRS complex in leads II, III, and aVF (superior frontal axis) suggests catheter position in the right ventricular apex (Fig. 5.10). If in the outflow tract, gentle withdrawal of the catheter will allow it to fall to a more inferior position and further advancement will guide it toward the apex. Deflating the balloon, then very gently advancing the catheter an additional 1 to 2 mm to wedge it in between the trabeculae of the right ventricle, can improve catheter stability. If positioning is performed *without* pacing, a pattern of ST-segment elevation on the local electrocardiogram indicates endocardial contact (Fig. 5.11).¹⁰⁵ The latter technique may be preferable in patients with complete heart block because even a brief period of overdrive pacing can extinguish a ventricular escape rhythm, resulting in immediate pacemaker dependency; therefore, transcutaneous pacing patches should be in place and available for use. If the pacing catheter has been advanced more than

40 cm without evidence of capture, it may have looped within the right atrium, or passed through the right atrium into the inferior vena cava. Either way, the catheter should be withdrawn with the balloon deflated, and then advanced again.

Once good contact has been established, the pacing threshold can be tested by reducing pacing output until loss of capture is noted on the monitor. Ideally, the pacing threshold should be less than 2 mA and sensing should be greater than 5 mV. To prevent inadvertent dislodgement during manipulation of the external pulse generator, the pacemaker should be sutured to the patient’s skin with a redundant loop in two locations. A chest radiograph should be performed immediately to rule out pneumothorax and document catheter position.

SPECIAL CONSIDERATIONS IN TEMPORARY PACING

CONTRAINDICATIONS

Transvenous pacing should not be attempted in patients with a known superior vena cava (SVC) stenosis, and any resistance encountered during advancement of an intracardiac catheter should prompt the use of fluoroscopy (Fig. 5.12). Similarly, the presence of a mechanical tricuspid valve is an absolute contraindication, due to the potential for irreversible catheter entrapment.¹⁰⁶ Patients with any significant coagulopathy or ongoing need for anticoagulation may be better served with transcutaneous pacing, if at all possible. If transvenous pacing is necessary, it should be performed under fluoroscopic guidance to minimize the risk of lead perforation. Femoral access may be preferable in these circumstances, particularly if the need for transvenous pacing is felt to be short-lived.

Figure 5.9 Paced morphologic appearance from right ventricular outflow tract. A paced QRS with a “left bundle branch block” morphologic pattern and “inferior” axis (positive QRS complexes in II, III, and aVF) suggests a pacing catheter position in the right ventricular outflow tract.

Figure 5.10 Paced morphologic pattern from right ventricular apex. A paced QRS complex with a “left bundle branch block” morphologic pattern and “superior” axis (negative QRS complexes in II, III, and aVF) suggests a pacing catheter position at the right ventricular apex.

Figure 5.11 Electrogram guidance to place a temporary transvenous pacing lead. The end of the electrode is connected to an electrocardiogram to guide positioning. The electrogram appearances within the superior vena cava (SVC), right atrium, inferior vena cava (IVC), and right ventricle (RV) are illustrated. When in contact with the RV, the electrogram demonstrates an injury current with ST-segment elevation.

Figure 5.12 Superior vena cava (SVC) stenosis. There is extensive entanglement of a temporary pacing catheter at the site of an SVC stenosis (black arrow). Any resistance encountered during catheter advancement should prompt the use of fluoroscopy.

SENSITIVITY AND THRESHOLD TESTING

Owing to the inherent instability of a balloon-tipped catheter, sensing and pacing thresholds must be checked at least on a daily basis. Failure to sense can result in inappropriate pacing and precipitate polymorphic ventricular arrhythmias in rare circumstances.¹⁰⁷ Failure to capture in a pacemaker-dependent patient has obviously deleterious consequences, and it is imperative that the device be programmed with an adequate safety margin, typically two times the measured

Figure 5.13 A 12-lead electrocardiogram demonstrating both capture (*red stars*) and failure to capture (*black stars*). Failure to capture can be easily recognized by the presence of pacing artifact without a subsequent QRS complex or T wave.

Figure 5.14 A 12-lead electrocardiogram demonstrating failure to sense. There is indiscriminate delivery of pacing artifact, independent of the underlying heart rate and rhythm (*black stars*). Pacing intermittently fails to capture when falling within the refractory period of the ventricular myocardium (*black arrows*).

threshold. Failure to capture can be easily recognized on the 12-lead electrocardiogram or telemetry monitor by the presence of pacing artifact without a subsequent QRS complex or T wave (Fig. 5.13). Failure to sense can be easily recognized by the indiscriminate delivery of pacing artifact, regardless of the underlying rhythm (Fig. 5.14).

INFECTION

Prevention of catheter-based infections is always important, but even more so in a patient who may ultimately require a permanent device. If a temporary pacemaker has been placed in emergent conditions, empiric coverage with a first- or second-generation cephalosporin is reasonable to minimize the likelihood of infection, particularly if femoral access has been chosen.

TIMING OF REIMPLANTATION

The timing depends on a number of factors, including (1) the stability of the temporary pacing system; (2) the pacing indication; and (3) ongoing contraindications to permanent implantation. In some circumstances—for

example, in the setting of fungemia or endocarditis—a prolonged period of transvenous pacing is required. Permanent, “active fixation” pacing leads with retractable screws can be inserted through a peel-away venous sheath, and then attached to a permanent pulse generator on the patient’s skin. In patients with recurrent ventricular tachyarrhythmias, a permanent defibrillator lead can be attached to an externalized defibrillator in the same fashion.¹⁰⁸ Permanent leads are more maneuverable than temporary leads, and the use of preformed stylets can facilitate delivery of the lead into the right atrium, if atrial pacing is desired. If AV synchrony is desired and SN function is normal, a VDD lead with atrial sensing and ventricular pacing capability can be placed.¹⁰⁹ In day-to-day clinical practice, dual-chamber and biventricular pacing with temporary pacing catheters is rarely, if ever, performed.

COMPLICATIONS OF PERMANENT PACEMAKER IMPLANTATION

Although pacemaker implantation is a well-established procedure with a low risk of major complications in

experienced hands, physicians working in the critical care setting should be aware of complications that may require rapid recognition and therapy. More common implantation and lead complications include lead dislodgement, pneumothorax, hematoma, perforation with or without cardiac tamponade, and infection. Other complications including arrhythmias, thrombosis, inadvertent placement of a lead within the left ventricle, twiddler's syndrome, and pacemaker syndrome will also be discussed.

The most common complications following pacemaker implantation include bleeding, lead failure, and pneumothorax.¹¹⁰ Higher complication rates are noted with less experienced operators.^{110,111} Elderly patients (≥ 75 years) are also at increased risk of early postoperative complications.¹¹² Body mass index, congestive heart failure, use of anticoagulants, and passive atrial fixation leads are also independent predictors for development of short-term (within 2 months) pacemaker complications.¹¹³

LEAD DISLODGEMENT

The incidence of lead dislodgement noted in clinical trials is 1.8% to 2.6%.^{4,114,115} Lead dislodgement rates depend on multiple factors and include lead fixation mechanism and operator experience. Active fixation (or “screw in”) mechanisms have reduced the frequency of this complication. Atrial leads may have higher rates of dislodgement than ventricular leads. Typically, lead dislodgement rates should be less than 3% with contemporary technology. Lead complications in general are more likely to occur with inexperienced operators.¹¹¹

Lead dislodgement may lead to increased capture thresholds, loss of capture (see Fig. 5.13), or loss of sensing (see Fig. 5.14). When a change in lead position is detectable by chest radiograph, this is referred to as “macro-dislodgement.” However, loss of capture or undersensing can also be seen with “micro-dislodgement” of leads, where there is no detectable change in lead position on chest radiograph. In some cases of micro-dislodgement, intermittent undersensing of intrinsic complexes or a change in pacing threshold may be corrected by reprogramming the pacemaker sensitivity or output. However, large changes in lead position typically require lead revision. Intermittent motion of the cardiac lead may also result in increased ventricular ectopy, with a premature ventricular contraction morphologic pattern that is similar to the morphologic pattern of the paced complex.

PNEUMOTHORAX

Venous access may be obtained through subclavian or axillary puncture, as well as cephalic vein cut-down. Complications related to venous entry include bleeding, arterial injury due to inadvertent arterial puncture, pneumothorax, hemothorax, thrombosis, air embolism, arteriovenous fistula, and brachial plexus injury. The risk of pneumothorax related to subclavian venous puncture is 1% to 2%,^{4,114} this risk may be reduced with contrast venography.

Pneumothorax typically presents early after the procedure, usually within 24 hours. Symptoms include chest pain, shortness of breath, or respiratory distress, which may be associated with hypotension or hypoxemia. Patients may

also be asymptomatic. Chest radiography is typically performed shortly after the implantation procedure to document baseline lead placement and exclude pneumothorax, even in asymptomatic patients. Chest tube insertion may be considered in patients who have pneumothorax that involves more than 10% of the pleural space.

CARDIAC PERFORATION

Cardiac perforation has been reported to occur in less than 1% of patients undergoing permanent pacemaker implantation.¹¹⁴ The risk may be higher in elderly patients, particularly elderly women, or those requiring anticoagulation. Perforation may not be initially detected, as some patients are asymptomatic. Alternatively, patients may report chest pain or shortness of breath. Lightheadedness or syncope may also occur, and can be associated with hemodynamic compromise in patients who develop cardiac tamponade due to a large pericardial effusion.

Signs of perforation may include pacemaker undersensing, increased pacemaker lead impedance, increased pacing threshold, loss of capture, or any combination thereof. Depending on the location of the perforation, diaphragmatic pacing or pericardial rub may also be noted. A change in the paced morphologic features from “LBBB” to “RBBB” in a patient with a single, right ventricular lead (Fig. 5.15A and B) is highly suggestive of a lead perforation and should be investigated further. Chest radiograph may show extension of the lead tip beyond the typical border of the right ventricle (Fig. 5.16). If loss of capture occurs in a pacemaker-dependent patient (Fig. 5.15C), higher pacing outputs may temporarily stabilize the situation, as long as the lead maintains some degree of contact with the ventricular myocardium. This is not a long-term solution but may obviate the need for transcutaneous or temporary transvenous pacing.

BLEEDING AND HEMATOMA

Hematoma is a common complication of pacemaker implantation, with increased risk in patients on anticoagulation. Although not life-threatening, a large hematoma can be quite painful, result in significant blood loss, and increase the risk of infection.¹¹⁶ In most cases, hematomas can be managed conservatively with observation and analgesia alone. Placing a pressure dressing over the site, immobilizing the ipsilateral arm in a sling, and temporarily withholding anticoagulation are often effective. However, in some cases, hematomas may become large and very painful, with oozing or drainage from the site (Fig. 5.17). When concomitant infection cannot be excluded, open wound exploration in a sterile setting should be considered. Needle aspiration of the hematoma should *never* be attempted at the bedside as this increases the risk of infection.

Precautions should be taken to reduce the risk of bleeding pre- and postoperatively. As with any surgical procedure, the risk of bleeding associated with device implantation must be weighed against the risk of interruption of anticoagulation. Official guidelines recommend “bridging” anticoagulation with heparin products in patients with mechanical valves, atrial fibrillation, and venous thromboembolic disease at “high” risk for thromboembolism.¹¹⁷ Nevertheless, there is a growing body of evidence in the

Figure 5.15 Lead perforation. **A**, A 12-lead electrocardiogram demonstrating sinus rhythm with synchronous ventricular pacing in a patient who had just undergone dual-chamber pacemaker placement. The paced morphologic pattern demonstrates a “left bundle branch block” appearance in lead V₁ (red star) with a leftward axis, consistent with normal lead position. **B**, A 12-lead electrocardiogram in the same patient demonstrating a “right bundle branch block” morphologic pattern in lead V₁ (red star) with a rightward axis, suggestive of lead perforation through the interventricular septum. **C**, Telemetry strip showing intermittent loss of ventricular capture shortly thereafter, due to progressive migration of the lead tip. There are sinus P waves with ventricular capture (green stars) and failure to capture (red stars) with pauses truncated by ventricular escape complexes (blue stars). The patient required emergent lead revision.

electrophysiology literature that continuation of warfarin may be safer than “bridging” with unfractionated and low-molecular-weight heparin.¹¹⁸⁻¹²⁰ There is no physician consensus about the optimal management of anticoagulation in this setting, but many physicians will implant pacemakers and defibrillators in fully anticoagulated patients.¹²¹ A patient with a compelling indication for anticoagulation may be better served by early initiation of warfarin, rather than a prolonged interruption of anticoagulation in the perioperative period. That being said, most operators

will not implant if the international normalized ratio is in excess of 3.0. In addition, most physicians will not implant devices while patients are actively taking dabigatran (Pradaxa) or rivaroxaban (Xarelto); this may change with accumulated experience, but these agents should be withheld for five half-lives (roughly 48 hours) to minimize the risk of bleeding. Because there is significant variability in practice patterns, communication with the implanting physician about anticoagulation management is strongly recommended.

Figure 5.16 Lead perforation. The lead tip extends to the lateral border of the cardiac silhouette, well beyond the typical border of the right ventricle (black arrow).

Figure 5.17 Hematoma. The edges of the hematoma at the site of pacemaker implantation are marked to follow the size and exclude continued expansion. A more erythematous area is noted on the medial lower edge of the hematoma. This may require drainage when large, tense, and painful, particularly if there is a need for early anticoagulation or if infection cannot be excluded.

Patients who have undergone device implant should not receive unfractionated or low-molecular-weight heparin for *at least* 6 hours after completion of the procedure, and low-molecular-weight heparin should be avoided in patients with significant renal insufficiency.¹²² Dual antiplatelet therapy also increases the risk of pocket hematoma,^{123,124} but these agents are not commonly held.

Thrombocytopenia and anemia are relative contraindications to device implantation, but a platelet count less than 50,000/ μ L and hemoglobin less than 7.0 g/dL are absolute contraindications for many implanters. Hematologic evaluation is recommended and transfusions may be necessary when pacemaker therapy is urgently required.

INADVERTENT LEAD PLACEMENT IN THE LEFT VENTRICLE

Very rarely, a ventricular lead may be errantly placed within the left ventricle. This may occur if the implanting physician inadvertently uses the subclavian artery for access, or if the pacing lead passes through a patent foramen ovale or atrial septal defect into the left atrium. Twelve-lead electrocardiography will typically show a RBBB morphologic pattern in lead V₁ during ventricular pacing, and lateral chest radiography will demonstrate a posterior lead position. Left ventricular access introduces significant risk of arterial thromboembolism and should be corrected immediately. If identified early after implantation, the lead should be easy to reposition.

ARRHYTHMIAS

The most common arrhythmias occurring after pacemaker implantation are ventricular ectopic beats, particularly in the very early postoperative period. These ventricular premature beats typically have a QRS morphologic appearance similar to the paced complexes. Ectopy often subsides within the first 24 hours, rarely requiring intervention. However, a change in lead position should be excluded by chest radiograph and bedside pacemaker analysis.

THROMBOSIS

Although venous thrombosis may be silent and not detected until the time of generator replacement and lead revision, symptomatic thrombosis is less common. Subclavian or axillary venous thrombosis may be detected early or late following implantation, and can present with upper extremity swelling and pain. This is typically managed with elevation and anticoagulation with heparin and then warfarin. More severe presentations of thrombosis, including superior vena cava syndrome or venous thromboembolic complications, are very rare.

LEAD FAILURE

Lead failure is typically due to fracture or insulation break, and this typically occurs long after initial implantation. Lead damage most often occurs close to the puncture site in the infraclavicular region (Fig. 5.18). Damage to the insulation may also occur at a site beneath the pulse generator due to abrasion, or may be the result of a suture being placed directly on the lead itself, in lieu of a suture sleeve. External trauma may also lead to lead damage and fracture.

Signs of insulation breaks include undersensing and reduced pacing lead impedance. Lead fractures may lead to high pacing lead impedance and loss of capture. Lead revision is indicated for lead fractures or insulation failure. Lead fracture typically requires replacement, but a localized insulation breach can often be repaired using a silicone repair kit.

TWIDDLER'S SYNDROME

Some patients may manipulate the pacemaker pulse generator, leading to dislodgement or fracture of the lead. This is called “twiddler’s syndrome.” Telemetry or

electrocardiographic findings may include loss of capture and loss of sensing. In addition to demonstrating lead dislodgement, the twisted leads within the pacemaker pocket may also be visualized on chest radiograph (Fig. 5.19A). Suturing the pulse generator to the chest wall may help reduce motion of the pulse generator, although patients should always be instructed to avoid manipulation of the pocket. The operative appearance of the leads at the time of pacemaker lead revision is illustrated in Figure 5.19B.

Figure 5.18 Lead fracture. Chest radiograph demonstrating unequivocal fracture of an atrial pacing lead (black arrow).

PACEMAKER SYNDROME

“Pacemaker syndrome” refers to a constellation of symptoms, such as fatigue, chest discomfort, dyspnea, cough, confusion, presyncope, or syncope, which are related to adverse hemodynamic effects resulting from loss of AV synchrony in patients with an implanted pacemaker. A significant drop in blood pressure may occur, and the diagnosis may be elusive in some cases unless specifically considered and confirmed by bedside evaluation. This can be corrected by reprogramming from the “VVI” mode to the “DDD” mode or “AAI” mode (in patients with intact AV conduction) or upgrading to a dual-chamber pacemaker, if a single-chamber ventricular device was implanted in a patient with sinus rhythm.

INFECTION

Care should be taken to avoid implantation of a permanent pacemaker in a patient with active infection, as this will increase the risk for device infection. Any active infection is a relative contraindication to permanent pacemaker implantation, although active bacteremia or fungemia are absolute contraindications. A fever or rising leukocytosis within 24 hours of implant should delay device implantation until a thorough investigation can be performed. Temporary pacing is appropriate in this setting, although that, too, has been associated with an increased risk of infection.¹²⁵ Patient characteristics also contribute to the risk of infection, and all modifiable risks should be optimized prior to device implantation.

Preoperative antibiotic administration has been shown to reduce the risk of device-related infection.¹¹⁶ There is no standard regimen, but most administer a penicillin or first- or second-generation cephalosporin for coverage of staphylococcus.¹²⁶ Patients with a history of methicillin-resistant *Staphylococcus aureus* (MRSA) colonization or infection, recurrent or prolonged hospitalizations, or either a penicillin or cephalosporin allergy should be given vancomycin.

Figure 5.19 Pacemaker lead dislodgement due to twiddler’s syndrome. **A**, Chest radiograph illustrating dislodgement of the atrial (open arrow) and ventricular leads (solid arrow) as well as significant lead entanglement in the vicinity of the pulse generator (arrowhead) in a patient with “twiddler’s syndrome.” **B**, Photograph taken at the time of lead revision, demonstrating significant entanglement of the leads.

Figure 5.20 Endocarditis. The echocardiographic appearance of a large vegetation attached to an atrial lead.

Patients with a history of vancomycin-resistant enterococcus (VRE) should be given either linezolid or daptomycin. There are limited data on the efficacy of postoperative antibiotic administration, but most implanting physicians empirically continue antibiotics for 24 hours after the procedure.

Careful attention to surgical technique and sterile procedures are important in preventing infection of the implanted pacemaker system. Pacemaker infection may be superficial or deep, with an incidence of less than 2% following initial implantation procedures, although it may be higher following generator replacement or lead revisions.^{4,127-129} Infections vary in severity from a superficial infection at the suture site with a local stitch abscess to a pocket infection or systemic infection with bacteremia. Erosion of the pacemaker pulse generator or leads may also be associated with infection.

Superficial skin infections or stitch abscesses may be treated and cured with antibiotic therapy. However, lead-associated endocarditis is a more serious complication and is associated with a high mortality rate. Systemic infections with bacteremia and endocarditis require device and lead extraction. Vegetations may develop on the pacemaker lead itself and become large, requiring extraction and removal of the pacing system for cure (Fig. 5.20). Infections may occur many months after device implantation, and hematogenous spread of organisms from a distant site may be a contributing factor. The most common organisms responsible for cardiac implantable electronic device infections are *S. aureus* (often methicillin-resistant) and coagulase-negative staphylococci followed by streptococci, enterococci, and gram-negative rods.^{130,131}

SPECIAL CONSIDERATIONS IN PERMANENT PACING

INTRAVENOUS ACCESS

The vast majority of permanent device implants utilize the cephalic, axillary, or subclavian vein. Implants using the

internal jugular and femoral vein are exceedingly rare. Devices are generally implanted on the nondominant side for reasons of patient convenience, but implants are usually less technically challenging on the left side. Devices should not be placed ipsilateral to the site of an arteriovenous fistula or graft, due to the short-term risk of vein thrombosis and long-term risk of vein stenosis.

If at all possible, subclavian access should be preserved in the critical care patient who may require permanent device implantation. If temporary venous access is required, the internal jugular or femoral vein should be used whenever possible. Peripherally inserted central catheter lines should not be placed ipsilateral to the side of the future permanent implant because of risk for venous thrombosis. Peripheral venography is not mandatory but can be helpful in very thin patients with a higher risk of pneumothorax and patients with signs of venous occlusion. It is therefore preferable to have an 18- or 20-gauge peripheral IV catheter in the upper extremity on the site of the planned implant, if at all possible.

MAGNET APPLICATION

Magnet application over a permanent pacemaker results in asynchronous pacing, such that pacing stimuli are delivered *regardless* of the underlying rhythm.¹³² Prolonged periods of asynchronous pacing should be avoided in the critical care setting, when concomitant metabolic and electrolyte derangement may increase the risk of proarrhythmia with “R on T” pacing. In contrast, a magnet placed over an implantable cardioverter-defibrillator suspends detection of ventricular arrhythmias, but it does *not* cause the device to pace asynchronously. In the critical care setting, magnet application over a permanent pacemaker can be used to confirm capture, evaluate the morphologic appearance of the paced complex, and terminate pacemaker-mediated tachycardia. In the defibrillator patient who experiences inappropriate shocks for rapidly conducted atrial fibrillation, lead fracture, or oversensing of physiologic signals, magnet application may be lifesaving.

MAGNETIC RESONANCE IMAGING

The vast majority of implanted devices are not approved for magnetic resonance imaging (MRI) scanning due to the potential for lead heating, changes in pacing threshold, and cardiac stimulation with proarrhythmia. Current guidelines do not impose absolute contraindications against the use of MRI, but they do strongly recommend against its use in pacemaker-dependent patients and in patients with defibrillators, except in highly compelling circumstances.¹³³ Based on expert opinion, patients with new implants (<6 weeks old), abandoned leads, passive leads, or epicardial leads, and pacemaker-dependent patients with defibrillators are ineligible for MRI, regardless of the clinical indication. Patients with temporary pacemakers are also ineligible, owing to similar concerns for lead heating and external interference.

If a patient with a cardiac device absolutely needs an MRI, close coordination with the electrophysiologist and radiologist is mandatory to minimize risk. The device should be programmed in an asynchronous mode with rate

responsiveness and other special pacing features deactivated to minimize the likelihood of unwarranted pacing. Cardiac resuscitation equipment should be immediately available, and device interrogation should be repeated immediately after the scan.¹³⁴ Within the last year, a new “MRI-compatible” pacemaker has become available for commercial use (*Revo MRI SureScan*, Medtronic, Minneapolis, MN). In selected patients with no alternative, lead and pulse generator extraction may be an option.¹³⁵

CONCLUSIONS

Multiple clinical trials have demonstrated the benefit of pacing therapy for the treatment of SND and AV conduction disturbances, as well as a variety of other conditions. Temporary pacing is particularly useful in the critical care setting and can be performed using a variety of techniques, including transcutaneous, transvenous, or epicardial approaches. Both temporary and permanent pacing can be associated with risks, but precautions can be taken to minimize risk whenever possible. Pacing may relieve symptoms, improve quality of life, or provide lifesaving therapy.

Many patients in the intensive care unit may develop bradyarrhythmias or have previously implanted permanent pacemakers already in place. Therefore, it is essential that critical care physicians are adept at arrhythmia recognition, recognize techniques for temporary pacing, and develop skills related to basic device troubleshooting to provide optimal care to patients in the intensive care setting.

KEY POINTS

- Bradyarrhythmias may be caused by either intrinsic dysfunction of the SN or AV conduction system, or may be due to a response of normal tissues to extrinsic factors.
- Temporary pacing is typically reserved for transient or reversible bradyarrhythmias, or when there is an ongoing contraindication to the implantation of a permanent device.
- Transcutaneous pacing is most appropriate in situations in which pacing is required only briefly or intermittently, or as a bridging measure for placement of a transvenous system.
- Complete heart block with a “junctional” escape rhythm does not typically require temporary pacing, unless accompanied by hypotension.
- Complete heart block with a “ventricular” escape rhythm usually requires temporary pacing, even if hemodynamically stable.
- There should be a very low threshold for temporary pacing in a patient with advanced second-degree AV block and history of syncope.
- Temporary pacing should be avoided in severely hypothermic patients due to the potential risk of catheter-induced ventricular fibrillation.

KEY POINTS (Continued)

- If there is an anticipated need for permanent pacing, the subclavian vein should be preserved for device placement.
- Heparin products, direct thrombin inhibitors, and factor Xa inhibitors should be withheld for at least 24 hours after pacemaker or defibrillator placement to minimize the risk of bleeding.
- It is imperative that the critical care physician recognize the electrocardiographic and radiographic signs of lead dislodgement and perforation.

Pericardial Tamponade: Clinical Presentation, Diagnosis, and Catheter-Based Therapies

Hani Jneid | Andrew O. Maree | Igor F. Palacios

CHAPTER OUTLINE

ETIOLOGY OF PERICARDIAL EFFUSION AND TAMPONADE

CLINICAL PRESENTATION

DIAGNOSTIC ROLE OF ECHOCARDIOGRAPHY

CATHETER-BASED DIAGNOSTIC AND THERAPEUTIC STRATEGIES

PERICARDIOCENTESIS

Indications

Technique

Complications

Management after Pericardiocentesis

Prevention of Recurrent Tamponade

OPEN SURGICAL PERICARDIAL WINDOW

PERCUTANEOUS BALLOON

PERICARDIOTOMY

Percutaneous Balloon Pericardiotomy Technique

Outcome Data after Percutaneous Balloon Pericardiotomy

Complications

OTHER PERICARDIAL INTERVENTIONS

Pericardial diseases have variable clinical presentations, including acute pericarditis, asymptomatic pericardial effusion, and pericardial tamponade. Although pericarditis is often a self-limiting disorder responsive to nonsteroidal anti-inflammatory drugs or steroid therapy, pericardial tamponade is a life-threatening condition and requires immediate therapy. Echocardiography and cardiac catheterization are important diagnostic tools and help in guiding therapies. Percutaneous catheter-based therapies, including pericardiocentesis and percutaneous balloon pericardiotomy, are safe and effective therapeutic modalities. Percutaneous balloon pericardiotomy is a relatively novel catheter-based technique that is gradually replacing the more invasive surgical pericardial window procedures. Pericardiectomy remains the definitive therapy for certain conditions, such as constrictive pericardial disease.

ETIOLOGY OF PERICARDIAL EFFUSION AND TAMPONADE

Pericarditis or pericardial effusion or both may result from an infectious, metabolic, inflammatory, autoimmune, or neoplastic process (Box 6.1).¹⁻³ The frequency of specific causes depends on the geographic location, time period, and characteristics of the populations studied. In one

European series of patients presenting with moderate and severe pericardial effusions, acute idiopathic pericarditis and iatrogenic causes accounted for most cases.¹ In a smaller series in the United States comprising patients presenting to a tertiary medical center with large pericardial effusions, malignancy was the most common cause.⁴ Pericardial effusions occurring after radiation therapy, myocardial infarction, and surgical and interventional cardiac procedures are increasing in incidence. Uremia and hypothyroidism remain important causes but are seen less frequently given the prompt diagnosis and treatment of these disorders.

Pericardial fluid can be either a transudate or an exudate. Although transudative effusions typically occur in patients with congestive heart failure, exudative effusions may occur with most types of pericarditis and are characterized by a high concentration of proteins and fibrin. Pericardial effusions may be serous (or serosanguineous), suppurative, or hemorrhagic. Although the presence of suppurative effusion is pathognomonic for an acute infectious cause, usually bacterial, hemorrhagic pericardial effusion is commonly related to chronic infections, with tuberculosis a classic example, particularly in developing countries. In developed countries, hemorrhagic pericardial effusions are likely to be iatrogenic or malignant in origin. In a retrospective analysis of 150 patients in the United States who underwent pericardiocentesis for relieving cardiac tamponade, 64% of patients

had a hemorrhagic pericardial effusion (with iatrogenic causes and malignancy accounting for most cases).⁵

CLINICAL PRESENTATION

The clinical presentation of patients with pericardial effusion varies. Some patients are completely asymptomatic, whereas others develop pericardial tamponade and cardiovascular collapse.

The normal pericardium is a fibroelastic sac composed of visceral and parietal layers separated by the pericardial cavity and containing a thin layer (20 to 50 mL) of straw-colored fluid surrounding the heart.³ The normal pericardium has a steep pressure-volume curve: It is distensible when the intrapericardial volume is small, but becomes gradually inextensible when the volume increases. In the presence of pericardial effusion, the intrapericardial pressure depends on the relationship between the absolute volume of the effusion, the speed of fluid accumulation, and pericardial elasticity. Although the rapid accumulation of small amounts of fluid (150 to 200 mL) can result in cardiac tamponade, the slow accumulation of larger effusions (>1 L, as in uremic pericardial effusions) is usually well tolerated.^{6,7} The clinical presentation is not only related to the size of the effusion, but also, and more importantly, to the rapidity of fluid accumulation.

Pericardial tamponade is a clinical syndrome with defined hemodynamic and echocardiographic abnormalities, which result from the accumulation of intrapericardial fluid and

Figure 6.1 The patient is a 61-year-old woman with recent tricuspid valve repair presenting with increased dyspnea, orthopnea, and pre-syncope. She was hypotensive and had distended jugular veins and distant heart sounds on physical examination. The hemodynamic trace depicts elevated right ventricular pressure with exaggerated respiratory variation consistent with pericardial tamponade.

impairment of ventricular diastolic filling.^{7,8} The ultimate mechanism of hemodynamic compromise is the compression of cardiac chambers secondary to increased intrapericardial pressure.⁸ Pericardial tamponade is usually a clinical diagnosis, with patients showing elevated systemic venous pressure, tachycardia, dyspnea, arterial pulsus paradoxus, muffled heart sounds, and evidence of electrical alternans on electrocardiogram (ECG).³ Pulsus paradoxus, which describes the exaggerated inspiratory decline in arterial blood pressure (>10 mm Hg), is largely attributed to inter-ventricular dependence within the confined pericardial space. Although its diagnostic utility was recognized many decades earlier,⁹ various conditions may lead to its absence in patients with cardiac tamponade (e.g., in patients with concomitant aortic regurgitation, atrial septal defects, severe left ventricular dysfunction, aortic regurgitation, severe hypotension, pericardial adhesions, pulmonary artery obstruction, or positive-pressure ventilation).⁸

The ECG shows sinus tachycardia and low voltage. Electrical alternans, which describes the beat-to-beat alterations in the QRS complex reflecting cardiac swinging in the pericardial fluid, is a relatively specific sign for tamponade and is rarely seen with very large pericardial effusions alone.¹⁰ Patients with pericardial effusions have an enlarged cardiac silhouette with clear lung fields on chest radiograph. The pericardial effusion has to reach 200 mL in volume to appear on the chest radiograph, and this volume occurs usually in slowly accumulating pericardial effusions (which are less likely to cause tamponade).¹¹ Rapidly accumulating small pericardial effusions may cause tamponade and have a normal chest radiograph.

The diagnosis of pericardial tamponade is best confirmed by a two-dimensional echocardiogram that shows a pericardial effusion, right atrial compression, and abnormal respiratory variations in the right and left ventricular dimensions and in the tricuspid and mitral valve flow velocities (Fig. 6.1).¹² The classic hemodynamic findings of pericardial tamponade include arterial pulsus paradoxus, elevation and

diastolic equalization of right and left ventricular diastolic pressures with pericardial pressure, and depression of cardiac output.⁸ Because patients with critical tamponade operate on the steep portion of the pericardial pressure-volume curve, drainage of even a small pericardial volume causes a dramatic reduction in intrapericardial pressure and rapid clinical and hemodynamic improvement (by shifting the stretched pericardium back to the flat portion of the pericardium pressure-volume curve).⁸

DIAGNOSTIC ROLE OF ECHOCARDIOGRAPHY

Echocardiography is recognized as a particularly useful imaging modality for pericardial disease.^{13,14} Currently, two-dimensional echocardiography has become the gold standard diagnostic modality because it provides a highly sensitive and specific noninvasive imaging technique for pericardial disease.^{12,15} It is also an important tool for the longitudinal follow-up of pericardial effusions over time (given a class IIa recommendation in the American Heart Association/American College of Cardiology guidelines for the clinical application of echocardiography).¹² Classically, a persistent echo-free space throughout the cardiac cycle between the parietal pericardium and the epicardium is pathognomonic for pericardial effusion by M-mode echocardiography.¹³

Two-dimensional echocardiography allows delineation of the size and distribution of the effusion, including loculated effusions, and helps assess the success of pericardiocentesis. The echocardiogram also can provide a reasonable estimate of the total volume of the effusion.¹⁵ Circumferential effusion greater than 1 cm in width is considered large (>500 mL). Moderate effusions (100 to 500 mL) are usually circumferential but less than 1 cm, whereas small effusions (<100 mL) are usually localized posterior to the left ventricle and measure less than 1 cm. Classification criteria differ significantly among various echocardiographers and institutions. The typical echocardiographic signs of pericardial tamponade are listed in [Box 6.2](#).

The nature of the pericardial fluid is difficult to identify by echocardiography. Increased echogenicity is suspicious, however, for the presence of proteins or cells or both in the

pericardial fluid. Fibrin deposits localized in the epicardial surface can be identified as echogenic masses. In one study of 42 patients with tuberculous and viral or idiopathic pericardial effusions, intrapericardial echocardiogram abnormalities, such as a greater degree of pericardial thickening, frequency and thickness of exudative coating or deposits, and strands crossing the pericardial space, were useful criteria in the diagnosis of tuberculous pericardial effusion and in differentiating it from chronic idiopathic pericardial effusion.¹⁶

The classic echocardiographic signs of cardiac tamponade are right atrial and right ventricular diastolic collapse. The right atrium and right ventricle are compliant structures. As a result, increased intrapericardial pressure leads to their collapse when intracavitary pressures are only slightly exceeded by those in the pericardium. At end diastole (i.e., during atrial relaxation), right atrial volume is minimal, but pericardial pressure is maximal, causing the right atrium to buckle. Right atrial collapse, especially when it persists for more than one third of the cardiac cycle, is a highly sensitive but less specific sign for tamponade. Early diastolic collapse of the right ventricle (usually occurs in early diastole when the ventricular volume is still low) is present when the intrapericardial pressure exceeds the right ventricular pressure and is a highly specific sign for tamponade. Right ventricular collapse may not occur when the right ventricle is hypertrophied, or its diastolic pressure is greatly elevated. Left atrial collapse is seen in nearly 25% of patients and is specific for tamponade. Left ventricular collapse is less common because the wall of the left ventricle is more muscular. Dilation of the inferior vena cava with lack of inspiratory collapse (usually <50% reduction in its diameter) and swinging of the heart also are seen in patients with pericardial tamponade. Doppler echocardiography provides direct assessment of the ventricular filling patterns in pericardial tamponade.^{11,12,17,18} Patients with pericardial tamponade have a marked increase in tricuspid and pulmonary valve flow velocities and a marked decrease in mitral and aortic valve flow velocities during inspiration compared with normal subjects and patients with effusions but not tamponade. Changes in left atrial inflow pattern and exaggerated respiratory variations in pulmonary venous flow velocity also are observed. In one study aiming to correlate clinical and echocardiographic findings prospectively, the highest specificity (98%) was seen in patients with right atrial and right ventricular collapse plus abnormal venous flow.¹⁹ The sensitivity and specificity of any chamber collapse were 90% and 65%.¹⁹

In addition to echocardiography, computed tomography and magnetic resonance imaging are useful techniques in the evaluation of patients with pericardial disease. Their high resolution is useful in the assessment of pericardial thickness (particularly important in constrictive-effusive pericarditis) and in the detection of pericardial effusion, masses, and cysts.

Box 6.2 Echocardiographic Findings of Pericardial Tamponade

2. Right atrium collapse (>30% of cardiac cycle)
3. Right ventricular early diastolic collapse
4. Abnormal inspiratory increase in blood flow velocity through tricuspid and pulmonary valves and abnormal inspiratory decrease of mitral and aortic valve flow velocity
5. Respiratory variations of pulmonary and hepatic venous flow
6. Dilated inferior vena cava with lack of inspiratory collapse
7. Swinging heart

CATHETER-BASED DIAGNOSTIC AND THERAPEUTIC STRATEGIES

Cardiac catheterization historically has been the standard diagnostic modality for cardiac tamponade. Right-sided

Box 6.3 Cardiac Catheterization Findings of Cardiac Tamponade

1. Elevated filling pressures
2. Diastolic equalization of pressures
3. Absence or blunted y descent in the right atrium pressure tracing
4. Absence or blunted early diastolic dip in the right ventricular pressure tracing
5. Arterial pulsus paradoxus

heart catheterization can confirm the significance of a pericardial effusion and allows evaluation of hemodynamic changes occurring after pericardiocentesis. It usually shows two major findings in patients with pericardial tamponade: (1) elevation and equilibration of intracardiac diastolic pressures (usually 10 to 30 mm Hg) and (2) inspiratory increase in right-sided pressures and reduction in left-sided pressures (ventricular discordance), which are responsible for the presence of a pulsus paradoxus (Box 6.3).⁸ With equalization of intrapericardial pressures, the mean right atrial, left atrial, diastolic pulmonary artery, and right and left ventricular end-diastolic pressures all are within 5 mm Hg of each other. In addition to producing elevation in the central venous pressure, cardiac tamponade produces characteristic changes in the waveforms of the hemodynamic tracings. With increasing severity of cardiac tamponade, the “y descent” and the early diastolic dip in the ventricular pressure tracings are gradually obliterated and eventually disappear. The absence of the y descent in the right atrial tracing is an important finding in pericardial tamponade. As pericardial fluid is removed, the intrapericardial pressure usually returns to the intrapleural pressure level, and the right atrial waveform normalizes with the reappearance of the diastolic y descent. If the right atrial pressure remains elevated after the pericardiocentesis, however, and a prominent y descent appears, the diagnosis of effusive-constrictive disease must be considered.²⁰ Although the latter condition is infrequent, it may be missed in some patients presenting with tamponade in whom it usually causes significant morbidity until they undergo surgical epicardiectomy. Pulsus paradoxus is another hallmark of pericardial tamponade; however, it may be absent in many conditions, or alternatively may be present in patients without cardiac tamponade, as previously stated.

PERICARDIOCENTESIS

INDICATIONS

Pericardiocentesis is the technique of catheter-based aspiration of pericardial fluid. It is a diagnostic and therapeutic modality in patients with pericarditis with pericardial effusion, pericardial effusion with pericardial tamponade, and effusive-constrictive pericarditis.

When the diagnosis of pericardial effusion has been made, it is important to determine whether the effusion

is creating significant hemodynamic compromise. Many asymptomatic patients with large effusions do not require pericardiocentesis if they have no hemodynamic compromise, unless there is a need for fluid analysis for diagnostic purposes. In a prospective long-term follow-up of large idiopathic chronic pericardial effusion (up to 20 years), Sagrista-Sauleda and colleagues²¹ concluded that large idiopathic chronic pericardial effusions were usually well tolerated for long periods in most patients with severe tamponade; however, they may develop unexpectedly at any time. Although pericardiocentesis was effective in resolving these effusions, recurrences were common, prompting the authors to recommend referral of these patients for pericardiectomy when recurrence occurs.²¹ When cardiac tamponade occurs, the emergency drainage of pericardial fluid by pericardiocentesis is a lifesaving therapy in a patient who would otherwise develop pulseless electrical activity and cardiac arrest.

When performed, pericardiocentesis should achieve several objectives, as follows: (1) relief of tamponade, when present; (2) obtaining fluid for appropriate analyses; and (3) assessment of hemodynamics after pericardial fluid evacuation to exclude effusive-constrictive pericardial effusion. Elective pericardiocentesis is contraindicated in patients receiving anticoagulation and in patients with bleeding disorders or thrombocytopenia (platelet count <50,000/ μ L). Pericardiocentesis also is ill advised when the presence of pericardial fluid is not confirmed, and when the effusion is very small or loculated. When pericardial tamponade occurs, complicating acute aortic dissection, pericardiocentesis is contraindicated because of the risk of increased dP/dt and further hemorrhage and extension of the dissection. The patient instead should undergo direct aortic repair together with pericardial drainage in the operating room.

TECHNIQUE

Pericardiocentesis is most commonly performed via a sub-xiphoid approach under ECG and fluoroscopy guidance (Fig. 6.2A). Traditionally, pericardiocentesis has been performed in the cardiac catheterization laboratory with arterial and right-sided heart pressure monitoring. Today the procedure also is performed in the noninvasive laboratory, intensive care units, or even at the bedside under echocardiographic guidance.^{22,23} Whichever modality is used, it is a safe procedure when performed by appropriately trained personnel.

Pericardiocentesis is a procedure based on the Seldinger technique of percutaneous catheter insertion. After the administration of local anesthesia (1% to 2% lidocaine) to the skin and deeper tissues of the left xiphocostal area, the pericardial needle is connected to an ECG lead. The needle is advanced from the left of the subxiphoid area while aiming toward the left shoulder (usually under fluoroscopic or echocardiographic guidance; however, blinded procedures are undertaken in cases of extreme emergencies). Often, a discrete pop is felt as the needle enters the pericardial space. ST-segment elevation is seen on the ECG lead tracing when the needle touches the epicardium and helps confirm the needle position (see Fig. 6.2B). The needle should be withdrawn slightly until the ST-segment elevation

Figure 6.2 **A**, Diagrammatic representation of a pericardiocentesis procedure using the subxiphoid approach. **B**, The pericardial needle is connected to an electrocardiogram (ECG) lead. The needle is advanced from the left of the subxiphoid area aiming toward the left shoulder. ST-segment elevation is seen on the ECG lead tracing when the needle touches the epicardium. The needle should be retracted slightly until the ST-segment elevation disappears. **C**, After the pericardial space is entered with the pericardial needle, a guidewire is introduced in the pericardial space through the needle. The needle is removed, and a catheter is inserted in the pericardial sac over the guidewire (either anteriorly or inferiorly in the pericardial sac).

disappears. When the pericardial space is entered, a stiff guidewire is introduced into the pericardial space through the needle, which is thereafter removed, and a catheter is inserted into the pericardial sac over the guidewire (see Fig. 6.2C). The drainage catheter used (often a pigtail catheter, denoting its shape) has an end hole and multiple side holes. Intrapericardial pressure is measured by connecting a pressure transducer system to the intrapericardial catheter. Pericardial fluid is then removed. Samples of pericardial fluid should be sent for appropriate biochemical, cytologic, bacteriologic, and immunologic analyses to assist in the diagnosis of the cause of the effusion (the first sample is usually reserved for microbiologic studies).

In the presence of pericardial tamponade, aspiration of fluid should be continued until clinical and hemodynamic improvement occurs. The catheter is frequently left in place for continuous drainage and as a route to instill sclerosing or chemotherapeutic agents if needed. The catheter is secured to the skin with sterile sutures and covered with a sterile dressing. The success rate of pericardiocentesis increases and the incidence of complications decreases with the increasing size of the effusion.

COMPLICATIONS

The potential complications of pericardiocentesis include the laceration of the heart or a coronary vessel, sometimes causing fatal consequences. Puncture of the right atrium

or the right ventricle with hemopericardial fluid accumulation, arrhythmias, air embolism, pneumothorax, and puncture of the peritoneal cavity or abdominal viscera all have been reported. Acute pulmonary edema may infrequently occur when the pericardial tamponade is decompressed too rapidly.

Other approaches of pericardiocentesis include the right xiphocostal, apical, right-sided, and parasternal approaches. Although these approaches may be useful under certain circumstances, they are associated with greater incidence of complications. The right xiphocostal approach is associated with higher incidence of right atrium and inferior vena cava injury. Puncture of the left pleura and the lingula is more frequent with the apical approach, and puncture of the left anterior descending and the internal mammary artery is more frequent with the parasternal approach.

Echocardiographically guided pericardiocentesis is a safe and effective technique.^{23,24} In a series of 1127 therapeutic echocardiographically guided pericardiocenteses performed in 977 patients at the Mayo Clinic between 1979 and 1998, the procedural success rate was 97% overall, with a total complication rate of 4.7%.²⁴ Echocardiography allows identification of the ideal site of needle entry and trajectory and is especially useful in patients with loculated effusions. In contrast to pericardiocenteses performed in the cardiac catheterization laboratory, the left chest wall, rather than the subcostal, approach is often used with echocardiographically guided pericardiocenteses.

MANAGEMENT AFTER PERICARDIOCENTESIS

Pericardiocentesis does not completely evacuate the effusion in most cases, given particularly that active secretion and bleeding into the pericardial space may continue. It is best to leave the pericardial catheter in place for 24 to 72 hours after the initial fluid evacuation. The patient is admitted for continuous ECG monitoring and for assessment of the rate of pericardial drainage. The pericardial space should be drained every 8 hours and the catheter flushed with heparinized solution, and systemic antibiotics (usually a first-generation cephalosporin for empiric coverage of gram-positive bacteria) are administered for the duration of the catheter stay. Based on the cause of the effusion, the patient's clinical and hemodynamic condition, and the amount drained, the pericardial catheter is removed usually within 72 hours, and decisions for additional therapy are contemplated.

No special care is required after an uncomplicated pericardiocentesis. If pericardiocentesis is performed for cardiac tamponade, the patient is watched for signs of recurrent tamponade, and a follow-up echocardiogram is useful to monitor the resolution of the pericardial effusion and to detect signs of cardiac compression.

PREVENTION OF RECURRENT TAMPONADE

For many patients with pericardial effusion and tamponade, standard percutaneous pericardial drainage with an indwelling pericardial catheter is sufficient to avoid recurrence of pericardial effusion and tamponade. Patients who continue to drain more than 100 mL/24 hours 3 days after standard catheter drainage should be considered for more aggressive therapy. Reaccumulation of the pericardial fluid is particularly common in patients with malignant pericardial effusions. Additional therapeutic approaches are available to prevent pericardial fluid reaccumulation, including intrapericardial instillation of sclerosing agents, use of chemotherapy, radiotherapy, percutaneous balloon pericardial window, and surgical intervention.²⁵⁻²⁸ Reaccumulation of fluid with recurrence of cardiac tamponade has been considered a definitive indication for an open surgical pericardial window or for percutaneous balloon pericardiotomy.²⁹

OPEN SURGICAL PERICARDIAL WINDOW

Surgical procedures for creating a pericardial window range from a simple subxiphoid pericardial incision (pericardiotomy) to the removal of a variable portion of the pericardium (pericardiectomy). Although recurrence is higher with the pericardiotomy procedure, pericardiectomy often requires an anterior thoracotomy or sternotomy rather than a subxiphoid approach and is associated with a higher postoperative complication rate. Many physicians advocate the performance of subxiphoid pericardiotomy in critically ill patients with limited life expectancy, reserving pericardiectomy for patients with a relatively better prognosis.

Subxiphoid pericardiotomy allows for an adequate evacuation of the pericardial contents, direct inspection of the pericardial space to break down loculations, and the performance of pericardial biopsies and fluid sampling for

diagnostic purposes. The procedure can be done safely and quickly under local anesthesia and provides prompt and long-term relief. Subxiphoid pericardiotomy alleviates the need for repeated pericardiocentesis and more invasive and difficult open drainage methods. Overall, the symptomatic recurrence of pericardial effusion after a surgical window is reported in the literature to be 5%.

PERCUTANEOUS BALLOON PERICARDIOTOMY

Patients with a malignant pericardial effusion and tamponade are likely to be suboptimal surgical candidates because of their overall poor health conditions and limited life expectancies. Palacios and colleagues^{29,30} pioneered at Massachusetts General Hospital in Boston the technique of percutaneous balloon pericardial window (also called percutaneous balloon pericardiotomy) as an alternative and less invasive technique to surgical pericardial window. With this modality, adequate drainage of pericardial effusion is performed, and a pericardial window is created percutaneously under fluoroscopic guidance using a balloon-dilation catheter. The technique of percutaneous pericardial window is relatively simple and safe and is performed in the catheterization laboratory under local anesthesia with minimal discomfort. Conscious sedation with intravenous narcotics and a short-acting benzodiazepine is generally used.

PERCUTANEOUS BALLOON PERICARDIOTOMY TECHNIQUE

Percutaneous balloon pericardial window is offered as an alternative technique to the surgical pericardial window procedure for patients with persistent drainage from their indwelling intrapericardial catheter (≥ 3 days of >100 mL/24 hours drainage) or as primary therapy at the time of initial pericardiocentesis. The subxiphoid area around the indwelling pigtail pericardial catheter is infiltrated with local anesthesia (1% to 2% lidocaine). A small amount (5 to 10 mL) of iodinated contrast agent is injected in the pericardial space to help outline the parietal pericardium (Fig. 6.3A). A 0.038-inch stiff guidewire with a preshaped curve at the tip is advanced through the pigtail catheter into the pericardial space. The catheter is removed, leaving the guidewire in the pericardial space. After predilation of the skin and subcutaneous tissue along the track of the wire using a 10F dilator, a 20-mm-diameter \times 3-cm-long balloon-dilation catheter (Boston Scientific, Watertown, MA) is advanced over the guidewire and positioned to straddle the parietal pericardium. Care should be taken to advance the proximal end of the balloon beyond the skin and the subcutaneous tissue to avoid dilation of the skin and subcutaneous tissue (and the resultant formation of a pericardial-cutaneous fistula) (see Fig. 6.3B). The balloon is inflated manually until the waist produced by the parietal pericardium disappears (see Fig. 6.3C). Biplane fluoroscopy is helpful to ascertain the correct position of the balloon straddling the parietal pericardium with the left lateral projection being particularly useful (see Fig. 6.3B and C). Two to three inflations are usually performed to have adequate opening of the parietal pericardium. The balloon-dilation catheter is

Figure 6.3 Computed tomography image of a percutaneous balloon pericardiotomy procedure. **A**, Injection of a small amount of iodinated contrast material confirms the intrapericardial location of the catheter. **B**, A left lateral projection shows an inflated dilating balloon catheter without a waist, indicating the need to reposition the balloon catheter to straddle the parietal pericardium. **C**, The balloon catheter is in the correct position and appears straddling the parietal pericardium in the left lateral projection.

removed, leaving the stiff guidewire in the pericardial space, where a new pigtail catheter is advanced over it and left indwelling in the pericardial space.

Patients are admitted to a regular medical ward unit after a percutaneous balloon pericardiotomy procedure and do not require a coronary unit admission. The pericardial catheter is aspirated every 6 to 8 hours and flushed with heparinized solution (5 mL, 100 U/mL). Pericardial drainage volumes are recorded, and the catheter is removed when there is less than 50 to 75 mL of pericardial drainage in 24 hours. Chest radiographs are obtained to check for the development of pleural effusion resulting from drainage of the pericardial fluid.

OUTCOME DATA AFTER PERCUTANEOUS BALLOON PERICARDIOTOMY

Palacios and colleagues²⁹ reported the first human experience with the technique of percutaneous balloon pericardiotomy in eight patients with malignant pericardial effusion and tamponade. The technique was successful in all patients with no immediate or late procedure-related complications. The mean time to radiologic development of a new or a significantly increased pleural effusion was 2.9 ± 0.4 days (range 2 to 5 days). No patient developed recurrence of the pericardial effusion or tamponade at a mean follow-up of 6 ± 2 months (range 1 to 11 months). Five patients died from their primary malignancy at 1, 4, 9, 10, and 11 months. A success rate of 87% was reported in the multicenter percutaneous balloon pericardial window registry, which enrolled 130 patients between 1987 and 1994 in 16 centers.^{31,32} In this registry, three patients sustained pericardial bleeding and were considered to have a failed procedure and ended up undergoing surgical window procedures. Eight patients had recurrence of pericardial effusion (mean time to recurrence 54 ± 65 days), of whom seven ended up having surgical window procedures (with recurrence occurring in four of those patients).

COMPLICATIONS

Minor complications occurred in 13% of the patients.^{31,32} The development of a large pleural effusion remains the

major concern after percutaneous balloon pericardial window. Most patients develop a left pleural effusion within 24 to 48 hours of the procedure, which in most cases resolves spontaneously (presumably owing to the greater resorption capacity of the pleural surface). Thoracentesis or chest tube placement was required in 15% of patients with preexisting pleural effusions compared with 9% of patients without preexisting pleural effusions.^{31,32} It is desirable to aspirate most of the pericardial fluid before creating the window to limit the potential volume of fluid that can immediately leak to the pleural space. When the preprocedure chest radiograph reveals a large pleural effusion, the chance of requiring thoracentesis subsequent to the percutaneous pericardial window is higher, and the procedure should be performed only when its benefits outweigh the risks of thoracentesis or chest tube placement or both. It is not advised to perform the procedure in patients with marginal pulmonary reserve, as in postpneumonectomy patients, because the development of a pleural effusion may significantly compromise their respiratory function. Finally, an increased risk of bleeding from the pericardiotomy site occurs in patients with platelet or coagulation abnormalities. In these patients, a surgical procedure under direct visualization may be safer. Thoracoscopic techniques were developed to create a larger pericardial window and carry lower morbidity rates compared with open surgical techniques.³³ This technique allows adequate long-term drainage and the ability to obtain specimens for pathologic analysis.³³

OTHER PERICARDIAL INTERVENTIONS

Percutaneous pericardial biopsy (PPB) is a relatively safe and feasible technique in the cardiac catheterization laboratory, and it can increase the diagnostic yield of pericardiocentesis and pericardial fluid analysis. One clinical scenario in which PPB may prove to be of particular importance is in the setting of tuberculous pericardial effusion because *Mycobacterium tuberculosis* is rarely cultured and a positive acid-fast stain is infrequently obtained from the pericardial fluid (which makes tuberculosis, unlike malignant pericarditis, a commonly missed diagnosis without the technique of PPB). PPB is also less invasive than surgical biopsy, and

can be easily modified to obtain tissue samples from pericardial masses. PPB was initially described in 1988 by Endrys and colleagues,³⁴ who reported a series of 18 patients undergoing pericardial biopsy using an endomyocardial biotome, and showed that PPB can be safely performed using conventional invasive cardiology techniques. Margey and colleagues³⁵ reported a case series of seven patients undergoing PPB for pericardial effusion, in whom they obtained a total of five biopsy specimens per patient with no complications. They demonstrated that pericardial biopsy adds incremental diagnostic value to the analysis of pericardial fluid alone, as it confirmed the absence of malignant invasion in four patients with neoplastic disease and the presence of lymphocytic and organizing effusive pericarditis in one and two patients, respectively.³⁵ Catheter-based intervention techniques in the pericardial space gained further momentum after a number of patients undergoing arrhythmia catheter ablation were found to have epicardial foci for the arrhythmia that could only be approached from the pericardial surface. Cardiologists also recognized that the pericardial space could be safely approached percutaneously even without a large collection of pericardial fluid present. Epicardial ablation has therefore become a therapeutic strategy for epicardial scar-related reentry, which is recognized as an important cause of ventricular tachycardia (especially in patients with nonischemic cardiomyopathy). Sosa and colleagues³⁶ were the first to show that the pericardial space can be safely entered with a blunt-tipped needle via a subxiphoid approach under fluoroscopic guidance. One should be aware that pericardial effusion and tamponade can occur as a result of these novel pericardial interventions.

KEY POINTS

- Patients with pericardial effusion have a variable clinical presentation; some are completely asymptomatic, whereas others develop tamponade and cardiovascular collapse.
- Pericardial tamponade is a clinical syndrome with defined hemodynamic and echocardiographic abnormalities, which result from the accumulation of intrapericardial fluid and impairment of ventricular diastolic filling.
- Two-dimensional echocardiography allows delineation of the size and distribution of the pericardial effusion, provides a reasonable estimate of its total volume, and helps assess the success of pericardiocentesis.

KEY POINTS (Continued)

- Pericardiocentesis is the technique of catheter-based aspiration of pericardial fluid and is a diagnostic and therapeutic modality.
- Pericardiocentesis is most commonly performed via the subxiphoid approach under ECG and fluoroscopy guidance in the cardiac catheterization laboratory with arterial and right-sided heart pressure monitoring. It also can be performed in the noninvasive laboratory or at the bedside using echocardiographic guidance.
- Percutaneous balloon pericardiotomy is an effective therapy for recurrent malignant pericardial effusion and is a less invasive alternative to surgical pericardial window.
- Surgical pericardiectomy is the definitive therapy for patients with constrictive pericardial disease.

NEWER TECHNOLOGIES

The first and most widely utilized of the percutaneously placed cardiac assist devices, the intra-aortic balloon pump (IABP) displaces blood from the descending aorta during diastole, resulting in altered myocardial mechanics during systole. By raising diastolic perfusion pressure, the IABP has the potential to augment coronary flow. Unlike the majority of more recently developed and generally mechanically more complex devices, the IABP provides auxiliary rather than independent support of cardiac output. Although it uses complex software algorithms, it is the simplest of the invasive devices mechanically, is the lowest in profile, and is associated with relatively low failure rates. Its advantages include the feasibility of allowing insertion in the cardiac catheterization laboratory or operating room or at the bedside, as well as a relatively small footprint allowing placement in the vasculature with less morbidity than other devices in its class. The indications, complications, and relative effectiveness of the IABP have been studied extensively for nearly 4 decades. National Center for Health Statistics

data show that at least 37,000 intra-aortic balloons were placed in the United States in 2004,¹ whereas some estimates range to more than 130,000 by 2010. There were close to 20,000 used in high-risk percutaneous coronary intervention (PCI) among U.S. centers contributing to the National Cardiovascular Data Registry (NCDR) during a recent 3-year period.² The primary hospital location where IABPs are placed is highly variable depending on patient acuity and types of procedures performed in individual institutions, but the cardiac catheterization laboratory has become the primary site,^{3,4} and bedside placement in critical care units has declined to the low single-digit percentages.

HISTORY

Initial experiments aimed at altering the timing of phases of the cardiac cycle originated with animal experiments conducted by Adrian Kantrowitz in the early 1950s in the

laboratory of Carl Wiggers at Western Reserve Medical School.⁵ The focus was initially oriented toward improving coronary blood flow rather than augmentation of cardiac output. Appreciating that coronary flow (particularly in the left coronary circulation) occurs primarily in diastole, the concept was to delay the peak systolic pressure pulse to the diastolic phase of the cardiac cycle.⁶ During the subsequent decade, this was followed by animal experiments attempting to use the diaphragm to provide the power for diastolic augmentation by wrapping it around the distal thoracic aorta.⁷ Clauss and colleagues effectuated counterpulsation by withdrawing blood from the circulation during systole and restoring it during diastole,⁸ but it was the work of Mouloupoulos and associates⁹ that introduced counterpulsation with a carbon dioxide-filled tube synchronized to the electrocardiogram (ECG) in canines. Kantrowitz subsequently changed the gas to helium, used in modern IABPs because it has only 5% of the density of CO₂ and allows faster inflation-deflation cycles and greater precision in timing. In addition, helium is inert, although it is less soluble and potentially more toxic in case of gas leak in the circulation. The IABP was introduced in humans in 1967 (Fig. 7.1). Initial favorable experience with intra-aortic counterpulsation in critically ill patients in cardiogenic shock (CS)^{10,11} led to the first major multicenter trial. This trial demonstrated significant hemodynamic benefit but only a 17% survival to discharge rate.¹² A number of incremental improvements over the next 4 decades resulted in introduction of a percutaneous approach,¹³ a second lumen for guidewire support of balloon advancement through the circulation,¹⁴ increasing automation of the control consoles, and prefolded and progressively lower-profile balloons.¹⁵

PHYSIOLOGY

The classic concept of intra-aortic balloon counterpulsation involves inflation in synchrony with aortic valve closure, at the onset of isovolumic diastole and the appearance of the aortic valve closure, displacing blood comparable to the balloon's volume into the peripheral circulation during

diastole. To accomplish further unloading, and to prevent interference with left ventricular (LV) ejection, balloon deflation has traditionally begun before opening of the aortic valve and the beginning of LV ejection, although as discussed subsequently, this may not be the optimal algorithm. An example of the effects of balloon counterpulsation on systolic and diastolic pressure is seen in Figure 7.2.

Figure 7.1 Adrian Kantrowitz with an early model of a working intra-aortic balloon pump used in patients circa 1967, the year of the initial human experience with the device.

Figure 7.2 Systemic pressure response to an intra-aortic balloon pump. The console is set to trigger at 1:2, hence both unassisted and assisted systole and diastole are seen. Note decrease in systolic pressure with balloon counterpulsation (double arrow) and augmentation of diastolic pressure (area under curve in blue), thus decreasing afterload and increasing inflow pressure to the coronary and other vascular beds during diastole. EDP, end-diastolic pressure.

The hemodynamic response to institution of IABP is quite variable, and depends on a complex array consisting of the patient's intrinsic blood pressure, heart rate, heart rhythm, aortic compliance, overall peripheral vascular resistance, intravascular volume status, cardiac function, adjunctive pharmacotherapy, disease state of the coronary vasculature, and degree of preservation of coronary flow autoregulation. In addition, the exact location of the IABP in the vasculature, the volume of the balloon, the frequency of inflation (frequencies from 1:1 to 1:8 are available depending on manufacturer), and timing of inflation and deflation all play important roles. Thus, the "classic" response consisting of lowering the systolic blood pressure and augmentation of diastolic pressure may not be seen; this classic response is based on the initial experience in CS, which led to a 20% drop in systolic pressure and a 30% rise in diastolic pressure.¹² In fact, systolic pressure can increase secondary to improved cardiac output, can decrease, or can be unchanged, as can coronary blood flow. An important characteristic of the IABP in contrast to most mechanical assist devices is that it contributes to pulsatile flow, with theoretical benefits to end-organ perfusion beyond any actual change in mean flow or pressures.

DIASTOLE AND CORONARY BLOOD FLOW

Because the majority of coronary flow occurs in diastole, an increase in diastolic pressure has the potential to augment coronary flow as well as flow to other end organs. Diastolic pressure may in fact be augmented substantially, in part because balloon inflation is rapid, yielding an abrupt increase in volume and effecting a rapid rise on the pressure-volume curve. A variety of physical and biologic parameters, including compliance characteristics of the aorta and vascular bed, affect the degree of augmentation.¹⁶ The extent of peak pressure rise has been reported in a range from minimal to near doubling of diastolic pressure.^{17,18} However, increase in diastolic pressure and hence coronary perfusion pressure may not result in an increase in coronary flow because autoregulation modulates this potential and because in normal patients, end organs capable of autoregulation maintain flow without significant change.

Despite both several decades of experimentation in animal models and attempts to assess coronary flow in a variety of clinical settings in humans, the effect of IABP on coronary flow remains incompletely defined. Experimental and clinical data fail to show change in flow in native coronary arteries^{19,20} or in bypass grafts²¹ regardless of the severity of coronary stenosis.²² Although total coronary blood flow may not increase, coronary blood flow velocity has consistently been demonstrated to rise.^{17,23,24} In turn, data from a thrombolysis in myocardial infarction (MI) model suggest that the pulsatile waveform generated by IABP during diastole may contribute to improved time to coronary reperfusion without concomitant increase in coronary blood flow;²⁵ in all likelihood this improvement reflects the enhancement in peak flow velocity that may also help prevent reocclusion.²³ However, pulsatile flow may have additional benefit: in a randomized study comparing cardiopulmonary bypass with or without concomitant IABP, multiple parameters of whole-body perfusion were superior in the pulsatile flow setting.²⁶ In general, augmentation of

blood flow appears most likely to occur in patients in profound shock.^{17,24,27} Thus, most of the benefits of IABP are related to improvement in hemodynamics with secondary relief of ischemia. Amelioration of ischemia may in turn result in improved LV function and additional improvement in hemodynamics.

SYSTOLE AND MYOCARDIAL MECHANICS

Although the IABP is generally described as both improving myocardial oxygen supply and lowering myocardial oxygen demand, the predominant effect is the latter. This is based on decreased afterload and wall stress with increased stroke volume and cardiac output, in particular in patients with low-output states. In general, the magnitude of hemodynamic response is proportional to the extent of depression of cardiac function.¹⁶ Because stroke volume improves, heart rate stays the same or tends to decrease even as cardiac output rises. Reduction in LV end-diastolic pressure and improved cardiac output is associated with lower left ventricular heart filling and pulmonary arterial pressures, whereas systolic pressure typically decreases and mean blood pressure stays the same in hemodynamically stable patients. In patients in shock, mean blood pressure rises and systolic pressure may increase as well. When IABP placement results in improved end-organ perfusion, as evidenced by signs such as better urine output, the overall prognosis is generally improved.¹² Reduction in left-sided heart filling and pulmonary artery pressures also leads to reduced right ventricular (RV) afterload; thus, IABP insertion may be helpful in some patients with right-sided heart failure.²⁸ Although ejection phase indices tend to improve with unloading, the extent of augmentation of cardiac output is limited by the overall reserve in LV systolic function. Thus, at the extremes of ventricular dysfunction, even with excellent positioning of the balloon and timing as well as large IABP volumes, the IABP may not provide sufficient augmentation of cardiac output in some patients. A variety of other parameters have been used to assess the effect of IABP in shock, most prominently the cardiac power index (mean systemic pressure times cardiac index), which is the strongest hemodynamic correlate of outcomes.²⁹

EFFECTS ON ORGANS OTHER THAN THE HEART

The effect of IABP on flow to end organs other than the heart is also incompletely characterized. In the cranial circulation, as in the heart, net flow does not appear to increase in patients with a stable hemodynamic state. Further, with balloon deflation, there is some evidence for transient reversal of blood flow as well,³⁰ although this may be a consequence of early deflation (see discussion under "Timing"). Similarly, overall carotid flow is not changed in this setting.³¹ During hypothermia while patients are under cardiopulmonary bypass, pulsatile augmentation as obtained by the IABP does appear to improve cerebral oxygenation.³² Indirect evidence again suggests additional benefit in the setting of shock, with better cerebral blood flow, a setting in which there is modest clinical experience with using IABP in patients with refractory cerebral vasospasm.³³ Despite improvement in cardiac output with IABP, gastric tonometry has not shown improvement in the splanchnic

circulation in CS patients,³⁴ and renal vein thermolulution has failed to show improvement in overall renal blood flow.³⁵ In cardiac surgery patients who subsequently developed low-output syndrome, however, IABP did have a positive effect on gastric tonometry.³⁶

THE INTRA-AORTIC BALLOON PUMP APPARATUS

With the introduction of a separate guidewire lumen in the early 1980s,¹⁴ the safety of IABP placement improved significantly. Previously, bulky 12 F or larger devices were placed via a surgical approach through an end-to-side graft to the femoral artery, with substantial associated morbidity. The device was then advanced through the femoral and iliac systems without a guidewire, frequently at the bedside with no fluoroscopic guidance. This led to a high rate of major vascular complications, in particular, iliac artery dissection but also aortic perforation and IABP malposition. The introduction of the percutaneous approach did not alleviate these problems until a guidewire lumen was added.¹⁴

There were conflicting demands on balloon design: first, to minimize the central lumen size as part of reducing overall profile, and second, at the same time to maintain a large enough lumen both for guidewires that could provide safe passage through the circulation as well as sufficient diameter for high-fidelity hemodynamic recordings. One solution to the latter has been the introduction of a line of catheters with a fiber-optic pressure measurement sensor.³⁷ In general, the guidewire lumens are designed to accommodate guidewires in the 0.018-inch to 0.030-inch range. The gas exchange lumen is concentrically placed around the guidewire lumen. Improvements in technology allowed for the introduction of tightly folded balloons prewrapped around the central lumen (Fig. 7.3); previously, a cumbersome process that sometimes led to device failure required the operator to wrap the balloon just before insertion.

BALLOON DIMENSIONS

The available IABP catheters range in gas volume from 25 to 50 mL and in shaft lengths from approximately 60 to 72 cm. The actual length of the balloon segment varies by manufacturer and balloon volume: Commercial balloon lengths are in the range of 16.5 to 26 cm. Although balloon volume does affect the degree of diastolic augmentation³⁸ and cardiac output³⁹ and may be particularly important in patients with severe, refractory CS, little difference was found in IABP effectiveness between 32-mL and 40-mL balloons in one study,⁴⁰ and risk to the patient is significantly higher if inflated balloon diameter approximates or exceeds aortic diameter (see “Complications”). Thus the decision for IABP size is typically based on patient size and severity of hemodynamic compromise, with the 40-mL balloon used in approximately three fourths of patients.⁴¹ A special consideration for balloon volumes is patient air transport; rapid changes in altitude will lead to increased (during ascent) or decreased (with descent) volume, requiring monitoring to ensure that appropriate balloon volume is maintained.⁴²

Figure 7.3 Magnified cross-sectional view of prefolded intra-aortic balloon (a 7.5 French wrap). The prefolding was a significant advance in technology in the early 1980s because it eliminated folding at the bedside, a process that occasionally led to tearing of the balloon membrane, and substantially reduced the overall profile of the device at insertion. (Courtesy of Datascope, Montvale, NJ.)

Because it is essential to locate the balloon below the origin of the left subclavian artery at the upper margin and above the renal arteries at the lower (a “safe zone”; Fig. 7.4), the tolerances are relatively low. Studies looking at the length of this segment in Japanese patients found a range of 21 to 25 cm, with good correlation between patient height and length of this segment (although in the relatively short Japanese population, the balloon lengths frequently exceeded the “safe zone” length for individual patients).⁴³ Recommendations vary by manufacturer: A 50-mL size I is generally recommended for patients taller than 6 feet (183 cm), and the 25-mL is used for patients shorter than 5 feet (152 cm). Recent changes in technology have allowed for larger diameter balloons to be available for shorter patients (e.g., a 50-mL IABP on an 8 F shaft is now available for patients 5’4” [162 cm] and taller). In general, larger balloon sizes lead to improved unloading and augmentation with greater blood volume displacement. Early balloon models were designed to be occlusive during inflation, and experimental data have demonstrated optimal augmentation with 100% occlusion of the aorta.^{38,39} Such full occlusion is generally avoided because of potential trauma to the aorta, ischemia to the spinal circulation, or abrasion of the balloon, which might contribute to a risk of rupture. The generally accepted value for ratio of balloon to aorta size is 80% to 90%; in the study by Igari⁴³ in Japanese patients, the range of commercially available balloon diameters was noted to be 14 to 15 mm, whereas aortic diameter mean at the level of the renal arteries was 17.5 ± 3.2 mm, within the accepted 80% to 90% range, although at least one 50-mL balloon has an expanded diameter of 18 mm (Arrow International, Inc., Reading, PA). In an earlier study in Americans, 90% of midthoracic aortas were larger than 19 mm.⁴⁴ Balloons are typically made of polyurethane or polyethylene, with materials chosen to allow rapid inflation-deflation cycles and tolerate an average of 100,000 to

Figure 7.4 Location of intra-aortic balloon during inflation and deflation. Ideally the tip should be a few centimeters distal to the origin of the left subclavian artery and the proximal portion above the origins of the renal arteries, the “safe zone.” (Adapted from figure provided by Teleflex Medical, Limerick, PA.)

150,000 cycles per day. Experimental materials with heparin and hydrophilic coatings have been developed to address thrombosis risk and trauma to the vasculature during device passage^{45,46} but are not generally available.

BALLOON CONSOLE

IABPs are driven by complexly engineered consoles with extensive artificial intelligence designed to recognize electrocardiographic rhythms and hemodynamics, with the ability to trigger balloon inflation either from the ECG (including paced rhythms) or from pressure waveforms, although in some settings, such as during cardiopulmonary bypass, an automatic trigger at a preset rate can be used. Tachyarrhythmias and irregular rhythms have substantial influence on the effectiveness of the IABP, the former in part because of the disproportionately shorter diastolic filling periods, and the latter because of difficulties predicting the timing of occurrence of the dicrotic notch, although improved algorithms have been incorporated.⁴⁷ The central lumen of the balloon is typically connected to a transducer and separate ECG leads are connected to the console. A series of alarms identify leaks in the IABP circuit, high or low pressure, loss of trigger signals, blood in the gas line, low battery, and other anomalies that foreshadow or indicate impending or existing system failures. (Figure 7.5 demonstrates the control panel of a modern IABP console.) Modern IABPs using fiber-optic technology permit automatic calibration in patients after insertion and automatic recalibration on a periodic basis or whenever the algorithms detect a change in patient condition.

Figure 7.5 Intra-aortic balloon console showing continuous display of electrocardiogram, systemic pressure (note diastolic augmentation), and balloon pressure. (Courtesy of Datascope, Montvale, NJ.)

Figure 7.6 A modern intra-aortic balloon. A minimal size central lumen allows advancement over a guidewire. Low-profile balloons such as this one use fiber-optic cable for pressure monitoring. (Courtesy of Datascope, Montvale, NJ.)

PREPARATION

Balloon preparation requires establishing a vacuum in the gas lumen by drawing back on a large-volume syringe, and also flushing the central guidewire lumen (Fig. 7.6). If the procedure is to be done at the bedside without fluoroscopy, measuring the approximate distance along the course of the femoral and iliac arteries and then up the descending aorta is essential prior to IABP placement. The approximate depth to which it needs to be inserted should be noted on the shaft prior to beginning insertion. The ECG leads should be connected to the IABP console prior to introducing the catheter if ECG triggering is to be performed.

BALLOON INSERTION

Based on data from the Benchmark Registry, nearly two thirds of IABP insertions in the United States occur in the cardiac catheterization laboratory, one fourth in the operating room, and the remainder at the bedside in a variety of hospital locations. In contrast, outside the United States, the operating room and the catheterization laboratory each account for approximately 40% of placements, with the remaining 20% inserted at the bedside.⁴

The modern IABP is designed to be introduced percutaneously through the common femoral artery, which is the method used in 95% to 98% of cases, two thirds via the right common femoral artery.^{41,48} A variety of disease states affect the ability to freely pass the device to the central aorta, in particular atherosclerosis, but also spasm and congenitally small vessels. Preprocedure assessment of the vascular tree is important: Diabetics, women, and patients with small body surface area in particular have small femoral arteries,⁴⁹ and there is a corresponding higher rate of vascular complications in these patients.⁵⁰ Pulses at the common femoral artery and below must be carefully documented before catheter insertion, and if there is suspected or confirmed peripheral vascular disease, angiography of the abdominal aorta, iliac artery, and lower extremities should be considered. This step is frequently not practical in the emergency setting or in patients with renal failure; in elective situations noninvasive evaluation should be performed, including

Figure 7.7 Optimal access for placement of an intra-aortic balloon pump, right femoral artery, left anterior oblique view. The sheath entry is above the femoral bifurcation near the center line of the femoral head (circle). Note the location of the inferior epigastric artery (IEA; arrow). The lowest inflection of the IEA lies just above the inguinal ligament; punctures below this point have a lower likelihood of subsequent retroperitoneal hemorrhage.

ankle-brachial indices with pulse volume recordings, computed tomography, angiography, or magnetic resonance angiography.

FEMORAL ACCESS

Every effort should be made to ensure that femoral puncture is above the femoral bifurcation and below the inguinal ligament (Fig. 7.7). An excellent practice is to place a short 5 F or 6 F pilot sheath in the femoral artery and to perform angiography of the common femoral artery to confirm sheath entry below the inferior excursion of the inferior epigastric artery; punctures above this landmark correlate strongly with retroperitoneal hemorrhage.⁵¹ Puncture below the femoral head drastically increases the likelihood of puncture into the femoral bifurcation vessels (77% of femoral bifurcations are at or below the inferior margin of the femoral head⁴⁹), which in turn is associated with acute leg ischemia due to vascular obstruction, and pseudoaneurysm formation upon balloon removal is more likely because of lack of the anvil of the femoral head against which to perform manual compression. If the pilot sheath is found to have entered outside the common femoral artery on femoral angiography, consideration should be given to switching to the contralateral side. Using fluoroscopy to aid in puncturing the common femoral artery at a point over the lower half of the femoral head is a recommended technique to ensure proper sheath placement.

SHEATHLESS INSERTION

The use of a sheathless insertion technique has been recommended to reduce complications.⁵² Sheaths typically add between 0.6 and 0.8 mm to the overall diameter required to place a device, so the sheath for an 8 F balloon approximates 10 F in outer diameter. “Going sheathless” therefore has the advantage of having the device occupy less space in the common femoral artery and has been described as reducing vascular complications with an odds ratio greater than 2:1.^{53,54} Although retrospective analysis of large patient subsets presents compelling data that the sheathless approach is superior for reducing complications,⁵⁵ this finding has not been universally confirmed.^{50,56} The latest data suggest that about 80% of IABPs are inserted with a sheath.⁴¹ The sheathless approach is most compelling in diabetic patients, women, and patients with known peripheral vascular disease or small body surface area. Sheathless insertion of an IABP requires careful preparation of the tissue track to allow atraumatic entry of the balloon tip into the artery directly through the skin over a wire. Spreading of tissue and predilatation with a dilator are essential. Fibrosed tissue tracks or thickened/calcified arterial walls frequently resist sheathless entry. In some cases, a stiff guidewire provides an adequate rail along which to slide the naked balloon catheter into the vessel.

BALLOON ADVANCEMENT AND POSITIONING

Once suitable access is gained, guidewire passage to the aortic arch is ideally performed under fluoroscopic guidance. Without fluoroscopy at the bedside, approximating the distance from the femoral puncture to a point near the top of the descending aorta is imprecise and adds to the risk of trauma/ischemia to head and neck vessels, the aorta, or the renal arteries. In the critical care setting, transesophageal echocardiography is a suitable alternative to fluoroscopy for enabling precise balloon placement.⁵⁷ If fluoroscopy is not used, prompt postprocedure radiography to confirm location is imperative.

If guidewire passage meets resistance, alternative approaches include use of guidewires that are hydrophilic, steerable, or both.⁵⁸ If significant iliac stenosis is noted, balloon dilatation or stenting of the iliac artery is an accepted practice with high success rate both for achieving passage of the IABP and as an adjunct to preventing distal ischemia.^{59,60} As more cardiologists become skilled in endovascular intervention, the ability to perform combined iliac stenting and IABP placement is expanding.⁶¹

Once the balloon has been advanced to a point 1 to 2 cm inferior to the left subclavian artery origin (see Fig. 7.4)—typically near the top of the descending aorta—the guidewire is withdrawn and the central lumen flushed. The vacuum port (minus its one-way valve) is connected to gas line tubing that in turn is connected to the console, and the dead space is purged and then filled with helium. The central catheter lumen is connected to a transducer on the console. After triggering is initiated, typically on every other beat, fluoroscopy should be used to confirm balloon location and filling, and pressure contours should be evaluated for appropriateness of timing (see later discussion under “Timing”). Once the timing is considered satisfactory,

continuous pumping can be initiated. If necessary, the balloon should be repositioned with the console turned to standby to avoid trauma to the aorta.

The distal circulation should be assessed carefully after IABP placement. Distal ischemia is relatively common. The most likely cause of acute ischemia is obstruction of the artery by the catheter shaft itself. If ischemia occurs hours or days after insertion, the possibility of thrombus, typically secondary to stagnant blood in the confined space of a small or diseased vessel, should be considered as well. A technique for addressing distal limb ischemia—placement of a small sheath retrograde in the contralateral femoral artery and antegrade in the ipsilateral common femoral or superficial femoral artery—if performed by expert hands, can occasionally salvage an ischemic limb without forcing removal of the IABP⁶² (Fig. 7.8). There is some evidence that IABP inflation properties and hemodynamic effects may be superior in the patient positioned horizontally than with the

Figure 7.8 Percutaneous external femoral-femoral shunt for a patient with critical leg ischemia after placement of an intra-aortic balloon pump (IABP) in the right common femoral artery. The patient has an occluded right superficial femoral artery (SFA), so distal circulation depends on profunda femoris to superficial femoral collateral vessels. The antegrade sheath is placed directly into the profunda femoris. MTM, male-to-male adapter; PFA, profunda femoris artery. (From Merhi WM, Turi ZG, Dixon S, et al: Percutaneous ex-vivo femoral arterial bypass: A novel approach for treatment of acute limb ischemia as a complication of femoral arterial catheterization. *Catheter Cardiovasc Intervent* 2006;68:435-440.)

patient tilted at a 30-degree angle.⁶³ Postprocedure and subsequent monitoring of left arm pressures can lead to early diagnosis of inadvertent balloon advancement obstructing left subclavian artery inflow, a phenomenon to which the restless patient who flexes the thigh is predisposed.

ALTERNATE ACCESS ROUTES

Multiple alternatives to percutaneous femoral access have been described, all associated with higher complication rates. In part, this difference in rates is selection related: Patients with severe peripheral vascular disease have multiple comorbid conditions that affect IABP complications. In addition, introduction of a balloon into a peripheral vessel smaller than the common femoral artery or into a large central vessel through a surgical approach of necessity creates hazards associated with the introduction, maintenance, and withdrawal of the IABP.

Approaches described to date include the brachial, subclavian, axillary, iliac, transthoracic, and translumbar arteries. Although the brachial approach has been successful in isolated cases,^{64,65} and sheathless entry reduces the overall diameter of lumen encroachment to less than 3 mm, the potential for complications is substantial. They include not only vascular injury and ischemia of the hand but also potential neurologic consequences from formation of thrombus on an indwelling catheter underneath the origin of the right common carotid artery (as the shaft traverses from the right subclavian artery to the innominate artery) as well as under the left common carotid artery and subclavian artery origin.⁶⁶

Iliac insertion through a conduit has been used for patients in whom femoral access is not adequate or who are not candidates for ventricular assist devices: With retroperitoneal placement, patients can be at least partially ambulatory during prolonged counterpulsation.⁶⁷ Other routes of access that have been described are via the subclavian⁶⁸ and axillary arteries,^{69,70} with or without conduits, and generally with an eye toward allowing modest ambulation during prolonged IABP use. A transthoracic approach has been described, with placement via the ascending aorta into the standard descending aortic location.^{71,72} The morbidity rate associated with these surgical placements is significantly higher,⁷³ in part because they typically involve longer IABP indwelling times as well as the comorbidity issues already mentioned.

TIMING

The importance of IABP timing was understood from the time of the original Mouloupoulos study in 1962.⁹ The timing of balloon inflation and deflation is designed to optimize afterload reduction and enhancement of diastolic pressure without interfering with ventricular ejection. Classically, it was considered optimal to inflate at the aortic valve closure, as soon as aortic valve closure occurred, and to deflate near the onset of ventricular depolarization, anticipating the beginning of mechanical systole (Fig. 7.9). In fact, significant enhancements to IABP efficiency can be obtained with refinements to these concepts.

LATE INFLATION AND EARLY DEFLATION

Gross errors in inflation and deflation lead to failure to obtain benefit from IABP and occasionally to significant hemodynamic compromise. Early in the history of IABP deployment, it was appreciated that inflation throughout the period from closure of the aortic valve to its subsequent opening was necessary for optimal hemodynamic effect.¹⁶ Both late inflation and early deflation reduce augmented LV stroke volume and result in decreased peak diastolic coronary velocity;²³ the latter is demonstrated with transthoracic Doppler ultrasound, a tool that can potentially be used to optimize timing. An additional concern exists with early deflation: The abrupt decrease in IABP volume during diastole can lead to reversal of both coronary and other end organ (e.g., cerebral) flow back into the aorta, shunting blood from vital end organs.³⁰

EARLY INFLATION

Early inflation results in increased afterload late in LV ejection with consequent impairment of LV systolic function. The ejection phase is shortened, LV end-systolic pressure rises, and stroke volume decreases; inflation, in the range of 130 to 190 ms before the aortic valve closure, results in a 20% decrease in stroke volume.⁷⁴ This effect may not be seen if early balloon inflation is less pronounced; no hemodynamic effect was noted when IABP inflation occurred 50 ms before the aortic valve closure. Regardless, although early inflation theoretically lengthens diastole and allows for a longer period of diastolic augmentation, the net effect does not appear to be salutary. In addition, early inflation carries theoretical risks associated with the increased afterload and wall stress, including aneurysm formation and rupture in the peri-MI period.

LATE DEFLATION

Similarly, late balloon deflation could be expected to interfere with ventricular ejection and decrease stroke volume. In fact, somewhat counterintuitively, a similar 110- to 180-ms delay in IABP deflation appears to have salutary effects and is associated with a stroke volume increase of 18%,⁷⁴ which apparently results from both an increase in diastolic filling period and an augmented decrease in afterload later in the cycle. This finding confirms a prior observation by Kern and associates⁷⁵ and suggests that, in general, most operators have timed deflation too early. The beneficial effect occurs with timing deflation to be simultaneous with LV ejection; delaying deflation beyond the range described, however, raises concerns similar to those described for early inflation.

ELECTROCARDIOGRAM TRIGGERING

When the ECG is used as the trigger, the descending slope of the T wave correlates best with the onset of diastole³⁸ and is the usual timing for balloon inflation. Deflation is typically timed to the R wave, which denotes a short time delay after the onset of electrical systole. Algorithms were developed early to effect prompt deflation and prevent inflation in the setting of ectopy, and IABP software recognizes

Figure 7.9 Examples of timing of intra-aortic balloon pump inflation and deflation with 1:2 balloon pumping. **A**, Optimal timing results in mild lowering of systolic pressure with diastolic augmentation. Also shown are examples of early inflation before the aortic valve closure (**B**), late inflation (**C**), early deflation (**D**), and late deflation (**E**).

pacemaker spikes in contrast to QRS complexes as well. As in the findings described previously,^{74,75} deflation timed to the J point, with adjustment for the delay between onset of isovolumic systole and aortic valve opening, and perhaps slightly later, was shown early in the IABP literature to improve stroke volume.³⁸

OTHER CONSIDERATIONS

A common problem has been proper timing in patients with underlying arrhythmias. Atrial fibrillation has been particularly vexing, with unpredictable beat-to-beat intervals. An algorithm to predict the occurrence of the distance between the QRS and the dicrotic notch was developed in the mid-1990s.⁷⁶ Newer dicrotic notch prediction algorithms using high-fidelity micromanometer pressure sensors have been described.⁴⁷ However, atrial fibrillation poses difficulties beyond timing alone; rapid ventricular rates result in a disproportionate decrease in the diastolic interval and limit the effectiveness of IABP because of the inherently short period of counterpulsation,⁷⁷ including subtraction of the fixed time interval required for shuttling helium into and out of the balloon. Operating at 1:2 rates may be required in this setting.

Lack of augmentation despite proper timing should result in troubleshooting the IABP console, checking with fluoroscopy to visualize inflation of the balloon and confirm the level of balloon placement, and excluding kinking of the gas line or other mechanical failures. Apparently normal IABP function with absence of hemodynamic improvement should raise a suspicion that the patient has a baseline hemodynamic state that will not benefit from LV unloading, in particular hypovolemia, sepsis, or profound hemodynamic collapse, as well as a number of conditions described subsequently (see “[Contraindications](#)”).

Overall, timing of IABP should result in diastolic pressure augmentation and lowering of assisted peak systolic pressure when possible, with the former a generally used end point for patients with shock and the latter the primary goal in patients with more stable hemodynamics at the time of IABP insertion.

ADJUNCTIVE PHARMACOTHERAPY

Adjunctive pharmacotherapy typically includes heparinization. There are two theoretical reasons for anticoagulation: First, in patients receiving less than 1:1 counterpulsation, there is concern regarding clot formation on the balloon apparatus, and second, stagnant blood around the catheter shaft, especially in the common femoral artery, has been thought to raise the risk of thrombosis. The general consensus has been that anticoagulation should be administered if not contraindicated. The balloons themselves have a thrombogenic surface,⁴⁵ and occlusion of vessels requiring thromboembolectomy has been reported to be one of the most common complications, reaching nearly 3% in one series of 911 patients undergoing coronary artery bypass grafting (CABG).⁵³ Nevertheless, the thinking on this is in flux, with a growing evidence base that routine anticoagulation does not prevent thrombosis or thromboembolism but does increase bleeding risk. Thus, a recent study⁷⁸ compared

routine heparin use versus selective anticoagulation only in those patients with an indication for heparin use other than IABP insertion. There was no difference in the rates of IABP-related complications including major limb ischemia, but anticoagulated patients had a higher incidence of non-access-site bleeding, predominantly gastrointestinal. A randomized trial had similar conclusions, although the course of counterpulsation was relatively brief.⁷⁹ Review of the best evidence to date leads to the somewhat controversial conclusion that anticoagulation may be best targeted to selected patients who are at risk of thrombosis or thromboembolism for reasons other than IABP use alone.⁸⁰

A second adjunctive pharmacotherapy issue is the use of prophylactic antibiotics. Although fever, bacteremia, and sepsis were reported to be common (occurring at rates of 47%, 15%, and 12%, respectively) in one small study,⁸¹ the infection rate in larger series has been less than 1%,⁵³ and the consensus is that the evidence base is too thin and the public health implications too unfavorable to recommend routine antibiotic use unless otherwise clinically warranted.⁸² A third medication issue relates to sedation. Continuous bed rest in a critical care setting is frequently associated with disorientation or agitation. Balloon migration from leg bending and patient movement risks significant trauma to the aorta, renal arteries, and head and neck vessels. Careful sedation is essential. Finally, antiarrhythmic agents to slow and regularize the heart rate can have important benefits for lengthening diastole and optimizing balloon timing, both of which in turn enhance IABP augmentation.

BALLOON REMOVAL

Removal of the IABP poses several challenges. First, the ability to maintain hemodynamic stability without counterpulsation must be confirmed as part of the weaning process. Although cardiac output is disproportionately decreased with lowering of pumping ratios, such lowering appears superior to decreasing volumes as a weaning method, an approach confirmed by one small retrospective evaluation.⁸³ The balloon should not be turned off completely until the activated clotting time value confirms that anticoagulation has been effectively discontinued and the patient is ready for balloon removal, because thrombosis on the balloon surface occurs rapidly.⁴⁵ Most operators run the IABP at a low cycle rate, 1:3 to as low as 1:8 (depending on manufacturer), until anticoagulation has worn off sufficiently and the balloon can be removed. Nonfunctioning or stopped IABPs must be removed promptly, preferably within 20 minutes or less. A second challenge relates to the size of the deflated balloon. Because the balloon is delivered prefolded by the manufacturer (see [Fig. 7.3](#)), it passes readily through its delivery sheath during insertion. Once inflated, it will not refold when vacuum is applied, and the profile is too large for retrieval without bringing both the sheath and the balloon out of the body together.

Removing the balloon, especially after long indwelling times (mean indwelling time is 53 to 77 hours^{41,48}), requires meticulous attention to several details. First, the balloon gas line should be aspirated to reduce the balloon profile. Second, it is essential to allow some bleeding after catheter removal and prior to compression to avoid stripping any clot

off the balloon inside the common femoral artery. Because these are relatively large catheters, frequently deployed in patients with vascular disease who have a tenuous hemodynamic status even at the time of IABP removal, patients may not tolerate prolonged and aggressive compression of the groin. Recent discontinuation of heparin combined with a large arteriotomy size can result in significant difficulty in controlling hemorrhage and achieving hemostasis.

Surgical closure is sometimes preferable, particularly with severely obese patients, after very long indwelling times, with uncorrectable anticoagulation status, or with low or high punctures.⁸⁴ Vascular closure devices have been used successfully in small series^{85,86} but require extreme caution; significant mortality risk is associated with infections related to vascular closure devices,⁸⁷ and assuring sterility at the time of IABP removal is difficult. When use of a closure device is required, the authors typically place a 0.018-inch stiff guidewire inside the lumen after extensive efforts to achieve sterility of both the field and the device, withdraw the IABP, and place the closure device over the wire; we cannot recommend this off-label approach, however, until a better evidence base is available. Finally, it is important to continue to monitor patients for adverse events because nearly 25% of IABP-related complications have been reported to occur *after* IABP removal.⁸⁸

INDICATIONS

As with the original patients in 1968,¹⁰ CS remained the most common indication for several decades, although later data suggest that circulatory support for percutaneous intervention has replaced hemodynamic instability in the acute MI setting as the primary indication for IABP insertion.⁴¹ Other common indications are perioperative support for patients undergoing cardiac surgery, weaning from cardiopulmonary bypass, management of unstable angina, severe congestive heart failure, and with less evidence base, refractory ventricular arrhythmias or angina after MI as well as a host of miscellaneous settings largely defined by case reports (Box 7.1).

In general, indications can be divided into several categories: prophylactic versus therapeutic; hemodynamic support versus improved end-organ flow; and preoperative,

intraoperative, or postoperative management. The rate of prophylactic use, defined as IABP insertion prior to percutaneous or surgical intervention, rose from 17.3% in 1992 to 31.3% in 2001 as a proportion of IABP use in the United States according to the Benchmark Registry.⁴ The management and particularly the complications associated with these subcategories are substantially different. Box 7.1 lists indications for IABP use. The class I indications include CS if not quickly reversible with pharmacologic therapy, acute mitral insufficiency or ventricular septal rupture, recurrent ischemia or infarction, hypotension that does not respond to other interventions, and a low output state.

In general, use of an IABP identifies a high-risk population, with in-hospital mortality rate exceeding 20% among more than 22,000 patients (Fig. 7.10).^{4,48,89} The Benchmark Registry examined the use of IABP in more than 5000 patients with acute MI; this represented 24% of all IABP placements at the 250 participating medical centers. Twenty-seven percent of the patients were in CS, an additional 12% needed support because of acute ventricular septal rupture or severe mitral insufficiency, and 5% underwent IABP placement for refractory LV failure. Thus, nearly half the patients with IABP placements and MI had hemodynamic settings in which balloon support was considered potentially life sustaining.⁴⁸ Recent data confirm extensive IABP use in high-risk patients undergoing PCI: 44.4% of CS patients, 10.3% of patients presenting with ST-segment elevation myocardial infarction (STEMI), 28.1% of those undergoing left main PCI, and 13.9% of patients with LV function less than 30%.²

Despite general acceptance of its utility in salvaging myocardium and decreasing mortality risk (even without a strong evidence base), and despite a significant associated complication rate, there are no separate American College of Cardiology/American Heart Association guidelines for placing an IABP.⁹⁰ However, indications for IABP use are included in the Guidelines for ST-Segment Elevation Myocardial Infarction⁹¹ and in the more recent Guidelines for Percutaneous Coronary Intervention⁹²; hemodynamic support devices are currently considered a class I indication in the setting of CS, although as described subsequently, the evidence base is in flux. It is important to note that severe hemodynamic deterioration, including CS, is not limited to acute MI patients with ST-segment elevation.⁹³

Figure 7.10 In-hospital mortality rate in 5495 patients with acute myocardial infarction (MI) enrolled in the Benchmark Registry. Note the threefold higher mortality rate among patients with rescue placement of intra-aortic balloon pumps (IABPs) compared with those in whom IABPs were inserted preoperatively for high-risk surgery, and the continuing high mortality rate for patients with cardiogenic shock. Cath, cardiac catheterization; PCI, percutaneous coronary intervention. (Adapted from Stone GW, Ohman EM, Miller MF, et al: Contemporary utilization and outcomes of intra-aortic balloon counterpulsation in acute myocardial infarction: The Benchmark Registry. *J Am Coll Cardiol* 2003;41:1940-1945.)

Box 7.1 Indications for Use of an Intra-aortic Balloon Pump**Acute ST-Segment Elevation Myocardial Infarction (STEMI)*****Class I Indications**

Cardiogenic shock not promptly reversed with pharmacologic therapy
 Acute mitral regurgitation
 Ventricular septal rupture
 Recurrent ischemia and infarction
 Hypotension not responding to other interventions
 Low-output state

Class II Indications

Ila: Refractory polymorphic ventricular tachycardia
 IIb: Refractory pulmonary congestion

Additional Recommendations

In patients with cardiogenic shock after STEMI who are not candidates for revascularization
 As a short- or long-term mechanical support as bridge to recovery or heart transplant

Other Settings†**Percutaneous Intervention**

High-risk coronary angioplasty
 Acute coronary syndrome with hemodynamic instability
 Severe left ventricular (LV) dysfunction
 Unprotected left main vessel or single remaining vessel intervention
 Hemodynamic support for decompensated patients undergoing structural heart disease interventions

Cardiac Surgery

Preoperative use
 Severe LV dysfunction
 Left main vessel disease
 Acute coronary syndrome
 Repeat thoracotomy
 Perioperative or postoperative use
 Hemodynamic deterioration
 Inability to wean from bypass

Unstable Angina**Uncomplicated Myocardial Infarction (MI)‡****Congestive Heart Failure**

Fulminant myocarditis
 Decompensated aortic stenosis‡
 Drug toxicity‡
 Thyrotoxicosis‡
 Multiple sclerosis‡
 Lightning strike‡
 Right ventricular (RV) failure‡
 RV infarction
 After heart transplantation
 Bridge to transplantation

Miscellaneous

Cardiopulmonary resuscitation‡
 Noncardiac surgery
 Recent MI
 Left ventricular failure
 Unrevascularized myocardium
 Emergency surgery

†Based on available literature (cited in text) without formal guidelines.

‡Minimal or inconsistent evidence base for indication.

Class I, conditions for which there is evidence for or general agreement that the procedure is beneficial, useful, and effective; Class II, conditions for which there is conflicting evidence or a divergence of opinion about the usefulness or efficacy of a procedure.

Distribution of Indications from the Benchmark Registry³⁷

Cardiogenic shock	18.8%
Acute mitral regurgitation or ventricular septal defect	5.5%
Refractory arrhythmia	1.7%
High-risk percutaneous intervention	20.6%
Preoperative cardiac surgery	13.0%
Perioperative and postoperative cardiac surgery	16.1%
Unstable angina (including post-MI)	12.3%
Refractory congestive heart failure	6.5%
Miscellaneous or information missing	5.5%

CARDIOGENIC SHOCK

The classic understanding of CS has been stunning or irreversible loss of a large amount of myocardium ($\geq 40\%$) with resultant low output and compensatory elevated systemic vascular resistance to maintain central organ perfusion pressure. The definition of CS has varied, but the essential elements are persistent tissue hypoperfusion secondary to cardiac dysfunction in the presence of adequate filling

pressure (and elevated left-sided heart filling pressure). The most common current definition is hypotension (blood pressure < 90 mmHg systolic) for more than 30 minutes, with low cardiac index (less than 1.8 L/minute/ m^2 without support or less than 2.2 L/minute/ m^2 with support), and finally, elevated filling pressure (pulmonary artery wedge pressure > 15 mmHg or LV end-diastolic pressure > 18 mmHg or RV end-diastolic pressure > 10 - 15 mmHg).⁹⁴ Data from the SHOCK (SHould we emergently

revascularize Occluded Coronaries in cardiogenic shock) trial have called several classic assumptions into question,⁹⁵ in part because some of the patients in this trial with CS had relatively preserved ejection fractions, whereas other patients with apparently much larger amounts of dysfunctional or nonfunctional heart muscle were hemodynamically compensated.

Although the incidence of CS has declined,⁹⁶ it remains significant; the most recent estimates are that it is seen in approximately 6% of acute MIs. Mortality rate, once described as high as 80% (though variable in the literature, primarily because of the multiple definitions used), has declined in part because of better interventional tools,⁹⁷ because patients with coronary artery disease are receiving better long-term medical therapy, which in turn helps limit infarct size, and because the pharmacotherapy for CS itself has improved. Mortality rate remains high, however, with a nearly 40% in-hospital death rate reported in the Benchmark Registry.⁴⁸

IABP use in CS dates to the beginning of the IABP experience, and it results in predictable hemodynamic improvement in the majority of patients. IABPs have been shown to be beneficial in the setting of acute MI and CS when patients are *not* treated with PCI. The National Registry of Myocardial Infarction (NRFMI) 2 compared results in patients with CS who received adjunct IABPs and those who did not.⁹⁸ Although mortality rate was not affected in patients undergoing primary angioplasty, those receiving only thrombolytic therapy had a significantly higher mortality rate (67% without IABP vs. 49% with IABP). Similar findings were shown in the SHOCK trial⁹⁹ as well as a meta-analysis of more than 10,000 STEMI patients with CS.¹⁰⁰ A small and underpowered randomized trial also suggested that patients with Killip class III or IV heart failure after MI have lower mortality rates when treated with fibrinolysis combined with IABP than when treated with fibrinolysis alone.¹⁰¹ There is some basis for these findings from animal data, which suggest improved reperfusion when thrombolysis without other intervention is combined with IABP use.²⁵

INTRA-AORTIC BALLOON PUMP USE AS AN ADJUNCT TO REVASCULARIZATION IN CARDIOGENIC SHOCK

Figure 7.11 provides an algorithm for CS management; it is notable that IABP is at the center of the algorithm, and part of early management in all patients except those with rapid response to initial pharmacologic interventions. Based largely on indirect evidence, it has been assumed that use of IABP as an adjunct to coronary intervention in CS improves outcomes.¹⁰² Findings have included a nearly 60% reduction in the rate of major adverse events (ventricular fibrillation, cardiopulmonary resuscitation, prolonged hypotension) in the cardiac catheterization laboratory (odds ratio 2:1) after IABP insertion.¹⁰³ A trend toward lower 30-day and 1-year all-cause mortality rate has been demonstrated in patients in whom IABPs have been inserted within 1 day of presentation with CS,¹⁰⁴ albeit with a higher associated complication rate. Stabilization of patients with IABP and thrombolytic therapy and subsequent transfer for coronary intervention also appeared to have favorable

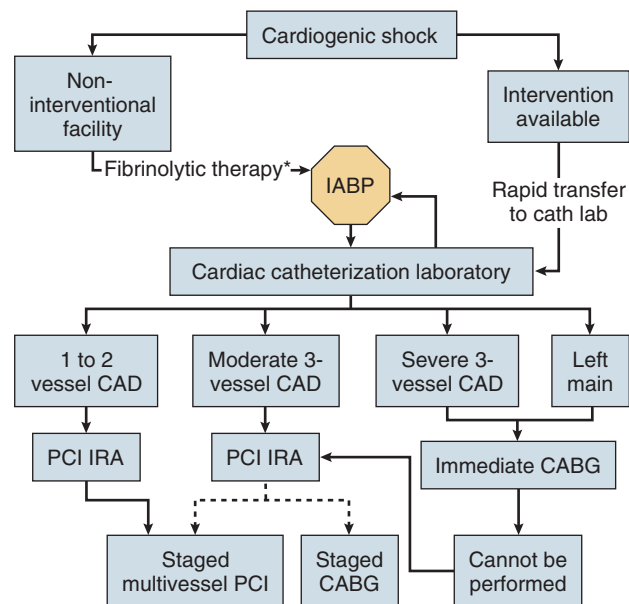

Figure 7.11 Algorithm for management of cardiogenic shock based on the SHOCK trial. Central to the treatment algorithm is rapid institution of intra-aortic balloon pump (IABP) treatment. For patients admitted to a hospital without interventional capacity, fibrinolytic therapy and IABP placement (if available) should be followed by rapid transfer to an interventional facility; if IABP treatment is unavailable, it can be started on the patient's arrival in the catheterization laboratory (cath lab) at an intervention-capable institution. *Fibrinolytic therapy should be given if there is more than a 90-minute delay until percutaneous coronary intervention (PCI) is available, less than 3 hours have passed since onset of infarction, and fibrinolysis is not contraindicated. CABG, coronary artery bypass grafting; CAD, coronary artery disease; IRA, infarct-related artery. (Adapted and modified from Hochman JS: Cardiogenic shock complicating acute myocardial infarction: Expanding the paradigm. *Circulation* 2003;107:2998-3002, used by permission of the American Heart Association.)

effects on survival,¹⁰⁵ mimicking animal data showing that reperfusion combined with IABP is superior to reperfusion alone in salvaging heart muscle.¹⁰⁶ IABP plus mechanical ventilation may also have incremental benefit in CS management.¹⁰⁷

However, a growing body of evidence suggests that IABP use may have at best modest benefits in CS when combined with acute intervention for revascularization. Most notably, the IABP SHOCK-II trial randomized IABP use in CS patients undergoing PCI.¹⁰⁸ No benefit of IABP was shown on 30-day mortality rate; a number of study design concerns exist (in particular between group crossovers and selection of a relatively low risk CS population) as well as the possibility that IABP placement before rather than after PCI (most patients had IABP placement after revascularization) would have shown additional benefit.¹⁰⁹ A smaller study, IABP SHOCK,¹¹⁰ demonstrated no significant improvement in serial APACHE (Acute Physiology and Chronic Health Evaluation) II scores with IABP use. Several meta-analyses have come to similar conclusions,^{100,111} albeit with evidence that IABP does have more readily demonstrable hemodynamic benefit; a more detailed examination of a small subset of patients did not confirm these hemodynamic benefits when

compared to medical therapy alone.¹¹² The bottom line, that the routine use of IABP in CS patients undergoing PCI should remain a class I indication, is thus under considerable scrutiny.¹¹³

An important consideration for the use of IABP in shock is that the cause should not be hypovolemia. Similarly, patients with shock and preserved systolic function are unlikely to benefit; settings such as vigorous ejection fraction in patients who have volume-depleted hypertrophic left ventricles may lead to deterioration with IABP placement, even without outflow obstruction, whereas use of the device with dynamic outflow obstruction can lead to hemodynamic collapse.

Finally, consideration has been given to the use of IABP in RV infarction; isolated RV failure occurs in approximately 3% of patients with CS.¹¹⁴ In this setting, patients commonly have severe hemodynamic decompensation and their overall prognosis is poor;¹¹⁵ within the cohort of patients with CS, however, RV dysfunction is associated with inferior MI and a relatively better prognosis than CS based on LV dysfunction alone.¹¹⁶ IABP use does not reliably result in hemodynamic improvement with RV infarction, and a variety of RV assist devices have been investigated, including pulmonary artery counterpulsation¹¹⁷ and a right atrium–pulmonary artery bypass pump.^{117,118} An occasional consideration in RV infarction is right-to-left shunting across a patent foramen ovale because of acute elevation in right-sided heart filling pressures, which result in a gradient that drives right-to-left atrial flow. Unloading of the left ventricle with an IABP can potentially exacerbate such shunting.¹¹⁹

MECHANICAL COMPLICATIONS OF ACUTE MYOCARDIAL INFARCTION

Afterload reduction has significant hemodynamic benefits in patients with abnormal unloading of the left ventricle into the right ventricle (ventricular septal rupture) or left atrium (severe mitral regurgitation).¹²⁰ The theoretical effect of counterpulsation in lowering afterload is in improving the ratio of forward flow through the aortic valve. The physiologic benefit in acute mitral insufficiency (mitral regurgitation) is widely accepted, resulting in a higher percentage of patients with severe mitral regurgitation and CS receiving IABP support than patients with CS alone.¹²¹ The mechanism of benefit appears to be lowered aortic impedance with consequent improvement in cardiac output, and modest decrease in regurgitant fraction.¹²² The IABP is in use in nearly all (98%) patients in this setting undergoing mitral valve repair, compared with less than half (43%) of those treated without surgery, a difference also influenced by selection issues. As with acute mitral regurgitation, 75% of ventricular septal rupture patients in the SHOCK registry underwent IABP placement.¹²³ Although systolic pressure did rise (from a median 81 mm Hg to 102 mm Hg) with institution of IABP in patients with ventricular septal rupture, mortality rate was dismal in both groups. In-hospital survival rate was only 13% with ventricular septal rupture, compared with 45% with severe mitral regurgitation. Nevertheless, IABP use is an essential element of intervention in acute ventricular septal rupture, and one goal of therapy has been stabilization before closure of the defect is undertaken.¹²⁴

ACUTE MYOCARDIAL INFARCTION WITHOUT SHOCK

IABP use for uncomplicated acute MI is controversial. As with many modalities that lower myocardial oxygen demand, IABP theoretically helps decrease infarct size, even when reperfusion does not take place.¹⁰⁶ However, a number of older trials and two randomized trials from the past decade did not demonstrate compelling risk-to-benefit ratios with routine IABP use in acute MI patients undergoing PCI,^{125,126} nor did a more recent study assessing myocardial infarct size using cardiac MRI.¹²⁷ The findings conform to a meta-analysis that showed no benefit along with a small increase in stroke and bleeding.¹⁰⁰ Economic analysis did not demonstrate significant increase in hospital costs in patients randomly assigned to undergo routine IABP insertion in this setting.¹²⁸ The potential benefit of the IABP in maintaining higher infarct artery patency has been demonstrated in two randomized studies showing that an open artery is more likely at 5 days¹²⁹ and at 3 weeks¹³⁰ in patients randomly assigned to IABP placement.

IABP has been used to manage recurrent ischemia and malignant ventricular arrhythmias in the peri-infarction setting, although the evidence base for these indications is less compelling, and both are class II indications (see [Box 7.1](#)) in patients with STEMI.⁹¹

UNSTABLE ANGINA

IABP use in unstable angina dates from an era in which the available alternatives were medical therapy and coronary bypass surgery, and IABP was utilized to stabilize patients before they were taken to the operating room. In certain settings, such as severe left main coronary artery disease discovered in the cardiac catheterization laboratory or in unstable angina with attendant hemodynamic instability, this approach is still appropriate.¹³¹ Reducing myocardial oxygen demand frequently stabilizes these patients, and the IABP may have additional benefits during subsequent revascularization in the cardiac catheterization laboratory or operating room, as discussed later.

PROPHYLACTIC USE FOR CORONARY INTERVENTION

Prophylactic use of an IABP prior to PCI has generally been considered to be a sound strategy for high-risk patients, typically defined as having acute coronary syndrome with hemodynamic instability, severe LV dysfunction and extensive coronary disease, or left main/last remaining vessel intervention. Prophylactic IABP insertion in this setting had substantially better outcomes than rescue IABP placement according to retrospective multivariate analysis,¹³² including evaluation of high-risk patients with severely depressed LV ejection fraction¹³³ undergoing angioplasty and patients undergoing unprotected left main PCI,¹³⁴ though the level of evidence base was generally weak. BCIS-1 (Balloon Pump-Assisted Coronary Intervention Study) randomly assigned patients to elective use of IABP prior to PCI in high-risk patients. Whereas it failed to demonstrate a significant benefit, a nonsignificant trend to decreased mortality rate was seen (4.6% vs. 7.4%) and may reflect the underpowered

nature of the trial. There was significant crossover in this study as well; crossover tends to dilute the power of studies that examine the use of already available technology, particularly when there is a perception on the part of clinicians that the device is efficacious, even if the efficacy is unproven.¹³⁵ IABP use in this setting is currently class IIB,⁹² and is discussed further in this chapter under “[Newer Technologies](#).”

A partial explanation for the less-than-compelling evidence for the use of prophylactic IABP in this setting is the misconception that IABP provides adequate protection to allow prolonged ischemia in a critical vascular bed during coronary intervention. With total occlusion of flow to a large amount of myocardium, such as with unprotected left main angioplasty or angioplasty of a sole remaining vessel, hemodynamics may be preserved during the procedure, and ischemia and necrosis may be limited by lowering of myocardial oxygen demand effectuated by IABP. However, because cardiac output remains dependent on LV ejection, myocardial oxygen demand is substantially higher than when temporary cardiac or cardiopulmonary bypass is used, and significant stunning or necrosis or both of heart muscle can occur despite IABP use during high-risk angioplasty.

CARDIAC SURGERY

IABP is utilized in approximately 10% to 15% of patients undergoing cardiac surgery, with substantial rise in the rate in the past decade.¹³⁶ About half of this use is for coronary bypass patients; two-thirds of the CS patients in the Society of Thoracic Surgeons database had insertion of IABPs.¹³⁷ A number of studies have demonstrated a favorable influence on outcomes, including mortality rate.¹³⁸⁻¹⁴⁰ Nevertheless, there is considerable variability in use among centers, reflecting a lack of consensus regarding indications for preoperative IABP use.^{136,141} The vast majority of IABP insertions occur preoperatively.^{136,137} The effectiveness of this approach has been controversial. One small randomized trial of high-risk patients demonstrated lower mortality rate, higher postoperative cardiac index, and shorter intubation time, intensive care unit (ICU) stay, and hospitalization in patients with preoperative IABP placement.¹³¹ Mortality rate benefit was also observed in a retrospective single center experience¹⁴² as well as a meta-analysis.¹⁴³ In contrast, a propensity analysis suggested excess mortality rate in nearly 2,000 patients receiving preoperative IABP insertion compared with 28,000 who did not.¹⁴⁴ Because of the limitations of propensity analysis, it is possible that selection bias determined the unfavorable outcomes associated with preoperative IABP use. Patients most likely to benefit from preoperative IABP insertion are those with depressed LV function, unstable angina or recent MI, or left main coronary artery disease or those who are undergoing repeat thoracotomy.

Several mechanisms can be postulated for superior outcomes with preoperative IABP insertion. Counterpulsation can provide hemodynamic support during anesthesia induction and during the stress of surgery before cardiopulmonary bypass is begun.^{140,145} As already described, IABP with pulsatile flow during cardiopulmonary bypass also appears

to have favorable effects on end-organ perfusion^{26,146,147} with protection of both coronary and cerebral blood flow.¹⁴⁸ IABP insertion can also be used to assess prognosis; requirement for catecholamine support and overall hemodynamics 1 hour after institution of perioperative balloon pump insertion is highly predictive of overall outcome.¹⁴⁹

Although studies have reported the mortality rate in high-risk patients treated with IABP as high as 53%, preoperative placement of an IABP was associated with substantially lower morbidity and mortality rates (24%), while postoperative insertion, in this case creating bias toward late insertion in situations with bad outcomes, was associated with a 63% mortality rate.¹⁵⁰ In the STS database, operative mortality rate in CS patients, the majority of whom received IABP, was high, ranging from 20% with isolated CABG to 33% for CABG and valve surgery and 58% for CABG and ventricular septal repair.¹³⁷ Similarly, a nonrandomized study of patients with an ejection fraction of 25% or less compared patients who were treated with preoperative IABP with those who were not. Mortality rate was 2.7% in the former group compared with 11.9% in the latter group, despite the presence of New York Heart Association (NYHA) class III or IV heart failure in 92% of the former and only 55% of the latter.¹³⁸ Several other post hoc analyses have found results consistent with advantages of preoperative IABP.^{151,152}

Outcomes in addition to mortality rate that were superior in patients undergoing preoperative IABP insertion were duration of IABP support, length of hospital stay, and postoperative LV ejection fraction in a randomized study of high-risk patients with ejection fraction of 30% or less.¹⁵³ Similarly, preoperative use of an IABP in high-risk off-pump CABG patients appears to be favorable.^{154,155} Thus, although the evidence base is incomplete, the overall preoperative use of IABP is growing.¹³⁶ Cost analysis appears to be favorable; combining high-risk cohorts randomly assigned to receive preoperative IABP placement or not,^{131,145} costs were 36% less in patients with preoperative IABP insertion because of shorter IABP treatment time, shorter hospitalizations, and lower use of critical care facilities.¹⁵⁶

CONGESTIVE HEART FAILURE

IABP has been used successfully in a variety of settings that results in congestive heart failure, including fulminant myocarditis¹⁵⁷ and severe decompensated aortic stenosis.¹⁵⁸ On the basis of case reports, the device has also been helpful as adjunctive therapy for myocardial depression secondary to drug toxicity,^{159,160} myocardial contusion,¹⁶¹ anaphylaxis,¹⁶² thyrotoxicosis,¹⁶³ multiple sclerosis,¹⁶⁴ and even lightning strike.¹⁶⁵ Animal data suggest some benefit in the setting of RV failure;¹⁶⁶ the mechanism appears to be lowered pulmonary vascular resistance with consequent improvement in RV ejection.²⁸ IABP insertion has also improved outcomes in patients with acute RV failure after heart transplantation.¹⁶⁷

Finally, IABP has been used as a bridge to transplantation, typically with placement in the axillary or external iliac arteries to allow ambulation during prolonged counterpulsation.¹⁶⁸ With development of a range of LV assist devices designed for long-term implantation, the use of IABP for this indication has waned.¹⁶⁹

MISCELLANEOUS INDICATIONS

Limited data suggest that IABP placement during cardiopulmonary resuscitation has favorable effects.^{170,171} The device has been used in pregnancy in patients undergoing heart surgery with an eye toward preserving uterine and fetal flow during cardiopulmonary bypass.¹⁷² In patients at high risk for cardiac events during noncardiac surgery (e.g., recent MI, LV failure, unvascularized ischemic myocardium),^{173,174} IABP has been shown to have significant benefits for outcome,¹⁷⁵ although the evidence base consists largely of case reports;^{176,177} a randomized trial has not been performed. Prophylactic IABP insertion seems particularly appropriate in high-risk patients undergoing emergency noncardiac surgery.¹⁷⁷

USE OF THE INTRA-AORTIC BALLOON PUMP

Overall, the existing data suggest that IABP is underutilized. In more than 23,000 patients in CS reported by NRMI 2, only 31% were treated with IABP. As is the case for a number of other interventions, women were less likely to undergo IABP placement; there was an age and race difference as well, with lower rates in nonwhites and older patients.¹⁷⁸ A number of studies from the 1990s demonstrated less than 25% use of IABP in CS;^{104,179} this figure contrasts with 86% utilization in the SHOCK trial.¹⁰² Although some exclusion criteria in the latter may have improved suitability for IABP in the cohort enrolled in the study, the threefold higher use of the device in the SHOCK trial is consistent with wide underuse in clinical practice, similar to findings for a variety of pharmacologic and invasive interventions in acute MI.⁹⁰

CONTRAINDICATIONS

The classic absolute contraindication to IABP use is aortic insufficiency (Box 7.2). Because the acute hemodynamic effects are so deleterious, animal and clinical investigations

Box 7.2 Contraindications to Use of Intra-aortic Balloon Pump

Absolute Contraindications

Aortic insufficiency*
Aortic dissection
Aortic aneurysm
Patent ductus arteriosus
Comorbidity with minimal survival expectancy
Brain death

Relative Contraindications

Hypovolemia
Severe peripheral vascular disease
Hypertrophic obstructive cardiomyopathy
Sepsis
Bilateral femoral-popliteal bypass grafts

*No evidence base exists for a minimal level of aortic insufficiency constituting an absolute contraindication.

all date to the 1970s.¹⁸⁰ Increased retrograde volume displacement into the left ventricle during diastole greatly exacerbates wall stress, with greater potential for hemodynamic decompensation as well as LV pseudoaneurysm formation and LV rupture in the post-MI setting. The amount of aortic insufficiency that constitutes an absolute contraindication has no objective basis, but most operators use a threshold of trivial to mild. Similarly, the presence of aortic dissection or aortic aneurysm is considered an absolute contraindication because of the risk of extending dissection or causing aneurysmal rupture. Patent ductus arteriosus, like aortic insufficiency, theoretically has deleterious results from shunting of blood flow from the aorta with IABP induction, in this case increasing left-to-right shunting into the pulmonary artery. Generally, patients who have severe comorbid conditions at end of life or who exhibit brain death are considered to have contraindications to IABP placement.

Relative contraindications include placement of an indwelling foreign body into a patient with active infection including sepsis, severe peripheral vascular disease likely to result in limb ischemia, bleeding diathesis (although in practice, many patients who have low fibrinogen levels or are receiving aggressive anticoagulant or antiplatelet treatment undergo IABP placement), and contraindications to afterload reduction, such as dynamic LV outflow obstruction,¹⁸¹ a condition that has on occasion been unmasked by institution of counterpulsation.¹⁸² Patients with shock due to severe hypovolemia will not benefit from insertion and may deteriorate with IABP-induced afterload reduction.

COMPLICATIONS

From the initial experiences with IABPs in the 1960s, the significant complication rate has been the single largest drawback to its use (Table 7.1). The predominant complications have related to the access site, with bleeding and limb ischemia being the most common, but they also include infection, thrombocytopenia, stroke, device failure, and a variety of vascular misadventures. Table 7.1 describes complications of IABP from multiple registries, trials, and case reports. The complication rate associated with IABP is affected by the insertion of indwelling, typically 7 to 10 F devices into the femoral artery of patients with a high prevalence of diabetes, peripheral vascular disease, and other major comorbid conditions. As would be expected, duration of IABP use correlates with risk of complications overall,^{183,184} including sepsis.^{185,186} Thus, frequent reevaluation of the patient to confirm ongoing need for IABP is prudent. Death due to IABP has been relatively uncommon, with the rate typically less than 0.3% to as low as 0.05%,⁴¹ and should be weighed against its considerable survival benefits.

The influence of procedure volume on outcomes has been demonstrated in a wide variety of cardiac procedures. Data from NRMI 2 found a significant correlation after multivariate analysis between number of IABP implants per year and CS mortality rate.⁹⁰ The study did not address complications related directly to IABP as a function of procedure volume for individual hospitals or operators. A higher rate of vascular complications was seen in the

Table 7.1 Complications with Use of Intra-aortic Balloon Pump (IABP) from the Benchmark Registry

Study Feature	All Benchmark Patients [†]	Patients with Myocardial Infarction Only [‡]
Year published	2001	2003
Total patients	16,909	5495
Reported Complication Rates		
All complications	7.0%	8.1%
Major*	2.8%	2.7%
Minor*	4.2%	5.4%
Vascular complications		
Limb ischemia	2.9%	2.3%
Major*	0.9%	0.5%
Vascular surgery	—	0.7%
Amputation	0.1%	0.1%
Hematologic complications		
Bleeding	2.4%	4.3%
Severe*	0.8%	1.4%
Infection	—	0.1%
Neurologic complications		
Stroke	—	0.1%
Death		
Due to IABP	0.05%	0.05%
Due to underlying morbidity	21.2%	20.0%
Others		
Deep vein thrombosis	—	0.1%
Bowel, renal, or spinal cord infarction	—	0.1%
Equipment malfunction	2.6%	2.3%
Balloon leak	1.0%	0.8%

*Major complications are major limb ischemia, severe bleeding, balloon leak, and death attributable to IABP insertion or failure; major limb ischemia consists of loss of pulse, loss of sensation, or abnormal limb temperature or pallor requiring intervention, arterial repair, or amputation; severe bleeding is defined as bleeding that requires transfusion or surgical intervention or results in hemodynamic compromise. Independent risk factors for major complications were female gender, peripheral vascular disease, body surface area < 1.65 m², and age ≥ 75 years.

[†]Based on data from Ferguson JJ III, Cohen M, Freedman RJ Jr, et al: The current practice of intra-aortic balloon counterpulsation: Results from the Benchmark Registry. *J Am Coll Cardiol* 2001;38:1456-1462.

[‡]Based on data from Stone GW, Ohman EM, Miller MF, et al: Contemporary utilization and outcomes of intra-aortic balloon counterpulsation in acute myocardial infarction: The Benchmark Registry. *J Am Coll Cardiol* 2003;41:1940-1945.

quartile of hospitals performing the most IABP insertions in high-risk PCI in the NCDR database,² but after multivariate adjustment this difference was no longer present, likely reflecting substantially higher morbidity in that patient population.

Comparing overall complication rates among different series is hindered by lack of uniform definitions, variable

demographics, comorbid conditions, duration of data collection, years when the data were collected (during which significant changes in technology may have occurred), and indications for IABP insertion. The rate of major complications has been reported to range from 2% to nearly 50%. However, the early data, which included surgical insertion, lack of a guidewire lumen for safer passage through the iliac arteries and aorta, and larger catheter and sheath sizes, were much worse than those in more recent series, with same center analyses describing as much as a fivefold decrease in major complications.¹⁸⁷ Thus, Kantrowitz and coworkers¹⁸⁸ reported a 47% complication rate over the first 15 years of IABP experience, and Alderman and colleagues¹⁸⁹ described a 42% rate of limb ischemia alone in their mid-1980s study. With improvements in technology, periprocedure pharmacology, patient selection, and management, the overall complication rates have declined to 15% in a large single hospital review published in 2000⁵⁰ and 6.5% in the Benchmark Registry, which incorporates the largest experience to date.¹⁹⁰ Although the series use variable definitions, the trend is unequivocal.

In general, diabetic patients and women have a higher complication rate,¹⁸⁸ coincident with the finding that these two populations also have significantly smaller femoral arteries.⁴⁹ A review of the existing literature on IABP complications shows peripheral vascular disease and female gender as nearly uniform markers of higher complication risk, with age, diabetes, size of catheter inserted, and smaller body surface area common but somewhat less consistent markers on multivariate analyses.^{41,50}

VASCULAR COMPLICATIONS

Vascular complications including limb ischemia are the most common serious adverse events related to IABP insertion. Amputation is rare (0.1%),⁴¹ but major limb ischemia, defined in the Benchmark Registry as “loss of pulse or sensation, or abnormal limb temperature or pallor requiring surgical intervention,” occurred in 1.3% of cases.¹⁹⁰ Minor limb ischemia, defined as not requiring surgery and improving with balloon removal, occurred in another 1.2% in the same series. These numbers are consistent with steady improvement over the past decade: A smaller but still substantial earlier series from India involving 911 patients (with a much higher proportion of diabetic patients and likely significantly smaller body surface area) reported a 5.9% incidence of major vascular complications, and 5.8% rate of minor vascular complications.⁵³ This series used a 9.5 F shaft IABP, which has been shown to have higher vascular complication rates than the 8 F shaft balloons that have been available for the past decade.¹⁹¹ Vascular complications, likely in part because of comorbid conditions, are associated with a much higher overall mortality rate—as much as a twofold increase.⁸⁸

Trauma to the aorta has been reported, with paraplegia caused by spinal necrosis due to subadventitial hematoma,¹⁹² cholesterol embolization to spinal and mesenteric arteries,¹⁹³ and aortic dissection¹⁹⁴ as well as no obvious cause in some patients. The presence of friable atheroma in the descending aorta has been associated with embolization.¹⁹⁵ IABP use has been identified as an independent predictor for neurologic complications of percutaneous

intervention, although whether this is due to embolic phenomena or confounding variables has not been established.¹⁹⁶

A complication particular to IABP is thrombocytopenia, occurring presumably because of destruction of platelets that adhere to the IABP surface, although the mechanism remains unclear. Critical care patients who have IABPs in place and are heparinized have a 7:1 odds ratio of a 50% drop in platelet count compared with patients without IABPs who are placed on heparin therapy at similar doses,¹⁹⁷ lowering the likelihood that heparin-induced thrombocytopenia is the etiologic factor.

MECHANICAL FAILURE

Several complications of mechanical failure of the balloon or console have serious consequences. Rupture of the balloon was more common early in the IABP era, with an incidence reported to range from 1.7%¹⁹⁸ to 5.2%.¹⁹⁹ Typically the diagnosis was made by the appearance of blood in the gas lumen, with triggering of alarms. The usual site of rupture has been at a point when the aorta is at its nadir in diameter along the course of the IABP. Small vessel size is associated with abrasion of the IABP (thus the observation that it is more common in women²⁰⁰ likely correlates with their smaller body surface area); similar concerns arise for larger balloon sizes. Rupture of the balloon with a major gas leak, a rare event, has been reported to cause stroke secondary to gas embolization.²⁰¹ Hydrophilically coated balloons hold some promise for further reducing the risk of rupture through potentially decreasing abrasion of the balloon surface.⁴⁶ Fracturing of the IABP can occur with entrapment, including separation and migration of part of the device.²⁰² Clot may also form in the gas lumen after loss of balloon integrity and has been reported to interfere with balloon deflation, requiring use of a thrombolytic agent in the gas line to allow balloon deflation and removal of the balloon.²⁰³

TREATING COMPLICATIONS RELATED TO THE INTRA-AORTIC BALLOON PUMP

Several approaches to managing IABP-related complications have been proposed. Limb ischemia has traditionally been most successfully treated by removal of the IABP,^{53,204} even in patients wholly dependent on the balloon, in order to avoid loss of limb. This situation has occasionally forced physicians and families to choose between loss of limb and patient survival. Surgical femoral-femoral shunting performed at the bedside with exteriorization of the graft has been described as one potential approach.²⁰⁵ As previously mentioned, we have performed percutaneous non-surgical external femoral-femoral shunting to effectively address limb ischemia by placing one sheath retrograde into the femoral artery contralateral to the IABP and another antegrade in the ipsilateral vessel, connecting the two sheaths with tubing and a flow regulator (see Fig. 7.5).⁶² Infusion of prostaglandin E₁ through the balloon central lumen has been shown to relieve lower limb ischemia in a small series, presumably through increase in caliber of collateral vessels or relief of spasm in the common femoral or iliac system.²⁰⁶

NEWER TECHNOLOGIES

Kantrowitz, who began this work more than a half century ago, attempted to develop a permanent implantable IABP. Initial results of a pilot trial demonstrated substantial improvement in hemodynamics. The ability to use the device intermittently rather than continuously, theoretically without thromboembolic risk once fully endothelialized, and its location downstream from the head and neck vessels differentiate it from other ventricular assist devices.²⁰⁷

A number of other percutaneous extracorporeal assist devices have been developed, although they lack the flexibility of bedside insertion and the low profile of the IABP (Fig. 7.12). The TandemHeart device (CardiacAssist, Inc., Pittsburgh, PA) is a left atrial to femoroiliac bypass, powered by an external centrifugal pump that provides up to 4 L/minute of forward flow. It requires transseptal puncture, institution of cardiac bypass with much larger arterial cannulas than the IABP (21 F in the left atrium, 15 F to 17 F in the iliac artery), and in general is more complex with greater risk of complications, as shown in a randomized study comparing the two approaches in patients presenting with CS being considered for PCI.²⁰⁸ It also cannot be shut off temporarily and requires more aggressive monitoring than balloon counterpulsation. Small randomized trials have been performed comparing the TandemHeart with IABP in patients with CS, demonstrating superior hemodynamics^{208,209} with the TandemHeart device.

The Impella device (Abiomed, Danvers, MA) uses a miniaturized axial flow rotary pump fitted onto a pigtail catheter. It is placed retrogradely across the aortic valve. It pumps blood into the aorta and directly unloads the left ventricle.²¹⁰ The Impella 2.5 and 5.0 provide maximal flow of rates of 2.5 L/minute and 5.0 L/minute, respectively. Unlike the TandemHeart, it does not require transseptal puncture or extracorporeal circulation with the attendant complexity and risks but does require insertion of substantially larger hardware into the femoral artery than the IABP: A 13 F sheath is required for the Impella 2.5, whereas the shaft of the 5.0 device is 21 F. Both devices appear promising for circulatory support in a variety of settings but, unlike IABP, do not provide pulsatile flow.²¹¹ Registry data utilizing Impella for high-risk PCI and for acute MI and CS showed consistent improvement in hemodynamics.^{212,213} There are minimal data comparing IABP to Impella in patients with CS, with one small trial showing superior cardiac output during Impella use but an identical mortality rate.²¹⁴ In the setting of high-risk PCI, the PROTECT II trial compared prophylactic IABP to Impella: Hemodynamics were superior with Impella, but overall outcomes including 30-day major adverse events were similar, with some later trends that appeared to favor Impella use, albeit with study design and enrollment issues that may have confounded results. A caveat to Impella use in this setting relates to a higher adverse event rate in the setting of rotational atherectomy.²¹⁵ In a meta-analysis of three of the randomized clinical trials described previously,^{208,209,214} hemodynamics consistently superior to IABP use were shown with TandemHeart and Impella, but these findings did not translate into a survival benefit;²¹⁶ it should be kept in mind that the TandemHeart and Impella devices are substantially more costly, complex

Figure 7.12 The TandemHeart device (**A**) draws oxygenated blood from a left atrial catheter placed across the interatrial septum and provides arterial return via a cannula placed into the femoral artery. The Impella catheter (**B**) draws blood from the left ventricle via a pigtail catheter placed retrograde across the aortic valve and pumps blood into the aorta. Although both devices actively provide systemic flow independent of left ventricular ejection, with superior hemodynamic results, neither delivers pulsatile flow and both require significantly larger arterial punctures than an intra-aortic balloon pump.

to institute and manage, and in the case of TandemHeart, appears to be associated with a higher complication rate.

Potential contraindications for both TandemHeart and Impella include aortic insufficiency and peripheral vascular disease. Aortic stenosis and presence of LV thrombus are contraindications for Impella use. Although post-MI ventricular septal rupture is uncommon, TandemHeart and Impella should be used with caution in that setting, because use of the devices could theoretically trigger right-to-left shunting because the substantial volume extraction from the left-sided heart circulation preferentially lowers LV pressure; however, despite the theoretical concern, a small series has documented benefit in this setting as well.²¹⁷ A number of other off-label uses of these devices have been described, including temporary support of the right ventricle²¹⁸ in RV infarction and as a bridge to ventricular assist devices and transplantation.

A vast array of other technologies is under development. The use of IABP in conjunction with assist devices that do not provide pulsatile flow may provide symbiotic preservation of end-organ circulation.^{219,220}

KEY POINTS

- The IABP is the most widely utilized cardiac assist device, featuring modest though significant risk, straightforward percutaneous insertion, and excellent hemodynamic support.
- There is a wide range of indications for IABP use, from prophylactic support prior to percutaneous or surgical intervention to stabilization in the setting of CS.
- Unlike more complex ventricular assist devices, the IABP does not independently generate systemic output; thus, it provides auxiliary support of cardiac function.
- The primary benefit of IABP is decrease in afterload and secondary improvement in hemodynamics; diastolic perfusion pressure is augmented but end-organ total flow is usually not increased directly.
- Timing of IABP inflation and deflation, absence of arrhythmia, and length of diastole all contribute to the effectiveness of IABP.
- There is a growing evidence base for limiting anticoagulation use to clinical settings when there are indications other than IABP placement.
- A small but significant complication rate remains associated with IABP use, in particular, vascular compromise and bleeding.
- The routine use of IABP for high-risk PCI and acute MI with CS is under extensive review based on recent randomized trials; methodologic considerations in these studies make their impact on future guidelines uncertain.

SUMMARY

Echocardiography has evolved to become a crucial noninvasive imaging modality in the critically ill patient. Its portability, safety, and widespread availability allow for the rapid diagnosis of life-threatening cardiac problems and rapid exclusion of cardiac disease in critically ill patients who present in an undifferentiated fashion. This chapter takes a systematic approach to the use of echocardiography in the critically ill, from the assessment of left ventricular (LV) and right ventricular (RV) function to valve disease, as well as pericardial disease, aortic disease, cardiac trauma, stroke, and rapid hemodynamic assessment.

APPROACH TO ECHOCARDIOGRAPHY

CARDIAC ANATOMY

Transthoracic echocardiography provides an excellent noninvasive means of assessing cardiac anatomy. Briefly, there are parasternal views, taken from approximately 2 cm leftward from the sternum and the fourth to fifth rib interspace, apical views, taken from the LV apex; subcostal views, taken from the epigastrium, and suprasternal views, taken from the sternal notch. Multiple images from different projections are needed to provide a complete view of the heart, manipulating the probe to provide long- and short-axis images of each structure interrogated.¹⁻³ The position of the echocardiographic transducer and the subsequent views produced are summarized in [Figure 8.1](#).

BASIC ECHOCARDIOGRAPHIC PRINCIPLES

Echocardiography uses ultrasound (i.e., sound above the audible range) to evaluate the heart and proximal great vessels and typically combines two modalities: tissue imaging (M-mode and two-dimensional [2D]) and blood flow detection with velocity determination (Doppler). Cardiac tissue imaging is based on the transmission of ultrasound into the chest and its reflection by intrathoracic structures, which is determined by their acoustic properties. The two imaging modalities in general clinical use are M-mode and 2D imaging.

M-mode uses a single scan line or beam to produce what is known as the “ice-pick” or one-dimensional view through intracardiac structures along the path of the ultrasound beam. It has the advantage of an extremely high sampling rate (1000-3000 Hz compared to 20-60 Hz for traditional 2D imaging) because only a single beam path is interrogated. M-mode is useful for measuring linear dimensions (such as chamber dimensions) and for appreciating high-frequency motion (i.e., the vibration of a torn leaflet), as well as for timing of events, especially valve opening and closing. However, M-mode provides a very limited field of view and is now primarily used as an adjunct to 2D imaging.

Two-dimensional images are obtained from multiple sequential scan lines generated electronically (phased array) and processed to create a tomographic imaging plane with an expanded field of view. The time required to obtain all necessary scan lines reduces the frame rate to the range

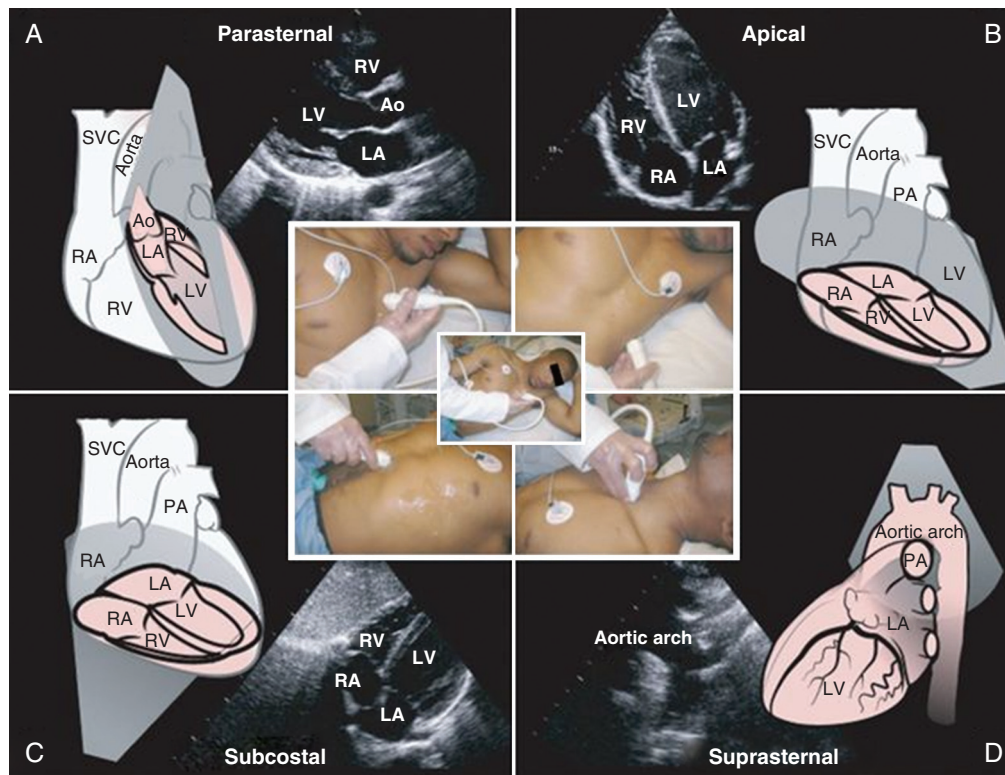

Figure 8.1 Line graphic demonstrating the four basic probe positions for transthoracic echocardiography. **A**, Parasternal long-axis (PLAX) imaging plane. **B**, Apical four-chamber (Ap4Ch) view. **C**, Subcostal view (Subx). **D**, Suprasternal notch view (SSN). Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

of 30 to 80 frames per second. Current ultrasound systems utilize both fundamental and harmonic imaging. Harmonic imaging transmits sound at a particular frequency (the *fundamental frequency*) but creates the image from sound reflected at twice the fundamental frequency, called the *second harmonic*, which improves image quality because the stronger harmonic signal undergoes considerably less distortion. This is particularly useful for endocardial border definition.

Doppler echocardiography uses ultrasound to determine blood flow velocity and direction within the heart. Two principal types of spectral Doppler techniques are used, termed *continuous wave* (CW) and *pulsed wave* (PW). CW uses two separate transducer crystals, one continuously transmitting and one continuously receiving the ultrasound signal. The high sampling rate of CW allows it to measure high velocities, but the source of any specific velocity measurement along the interrogated path cannot be differentiated (*range ambiguity*). On the other hand, PW uses one crystal, which alternates between sending and receiving an ultrasound pulse. The principal advantage of PW is that signals arise only from the area of interrogation, called the *sample volume* (*range resolution*); however, because the same crystal is used for sending and receiving the signal, a new pulse of ultrasound cannot be transmitted until the previous returning signal has been detected. This “pulsed” process results in too low a sampling rate to quantitate high velocities. PW and CW are thus complementary, with PW localizing the source of a signal and CW allowing for the unambiguous measurement of high velocities.⁴ Color flow imaging is a form of PW in which information is coded with colors and

superimposed on a 2D ultrasound image. Black and white identifies anatomic structures and color identifies blood flow velocities. Color Doppler has great utility in the evaluation of valvular regurgitant lesions and intracardiac shunts. An example of color Doppler identification of an atrial septal defect (ASD) with left-to-right shunting is shown in [Figure 8.2](#). Pulsed Doppler can also evaluate the velocity of moving myocardium, which produces a signal of low velocity but high amplitude, named tissue Doppler imaging (TDI). Systolic and diastolic velocities within the myocardium and at the corners of mitral annulus can be recorded. Mitral annular velocities as measured by TDI are commonly used to evaluate diastolic function.⁵

ADDITIONAL ECHOCARDIOGRAPHIC MODALITIES

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

When transthoracic echocardiography (TTE) image quality is suboptimal in certain patients in critical care—obesity, lung disease, uncooperative patient, ventilated patient, or when bandages or drainage tubes obscure the standard echo windows—transesophageal echocardiography (TEE) can be of great use.^{6,7} TEE involves insertion into the esophagus of an endoscope-like probe with an ultrasound transducer on its tip. Image resolution is improved with TEE because the ultrasound beam is unimpeded by bone and air, and because proximity to the heart enables use of high-frequency (7 MHz) probes. TEE can easily be performed at the

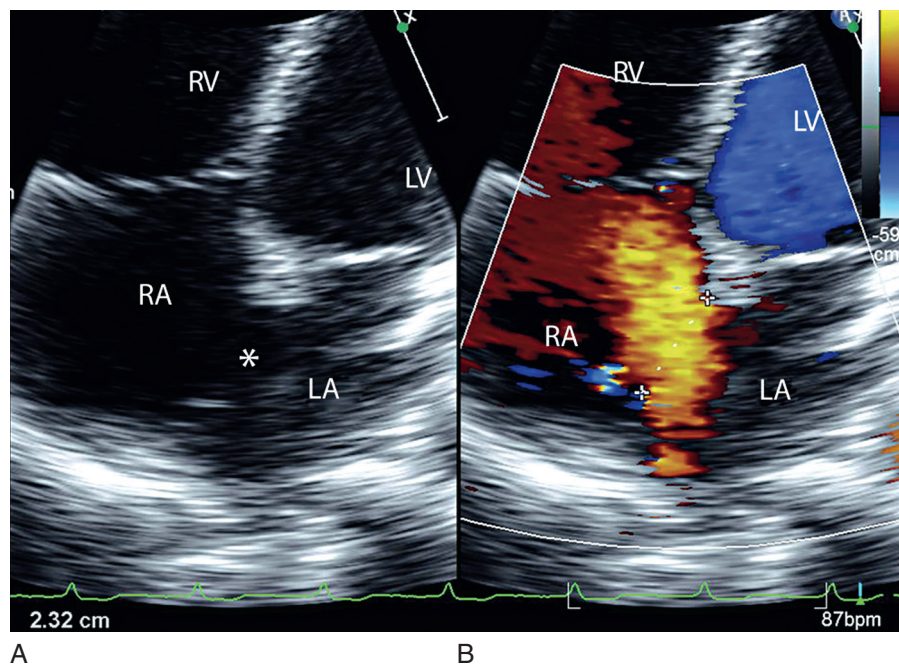

Figure 8.2 Color flow of secundum atrial septal defect (ASD). **A**, Apical image of dilated right-sided structures. Asterisk (*) indicates ASD. **B**, Color flow (orange) from left atrium through defect. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

bedside. Active esophageal disease is the major contraindication. A topical oral anesthetic spray is administered as well as an agent for conscious sedation. The TEE can be done with a nasogastric tube in place, but the nasogastric tube should be removed if there are any difficulties with passing the probe or in acquiring the images. Patients require blood pressure, respiratory, O_2 saturation, and heart rate monitoring during the procedure. A comprehensive transesophageal examination typically takes about 20 minutes for imaging, and then requires a period of recovery time.

CONTRAST ECHOCARDIOGRAPHY

SALINE CONTRAST

Echocardiographic contrast agents are substances that enhance the reflected ultrasound signal. Simple agitated saline contrast can be used to detect intracardiac shunts, commonly at the atrial level. To detect an intracardiac shunt, a contrast study can be done with agitated saline. In this technique, a 10-mL syringe containing 8 mL of normal saline is connected to a second 10-mL syringe containing 1 cm³ of air via a three-way stopcock. Brisk exchange of the saline between the syringes creates microbubbles, which are then rapidly injected as an intravenous bolus, resulting in opacification of the right chambers of the heart. Saline contrast bubbles are too large to pass through the pulmonary capillaries but may appear in the left atrium and left ventricle as a result of passage across an intracardiac (ASD or patent foramen ovale [PFO]) or intrapulmonary communication; occasionally, a cough or Valsalva maneuver may transiently increase right-sided heart pressures and facilitate right-to-left crossover of bubbles.⁸ Pulmonary arteriovenous malformations (AVMs) will demonstrate appearance of very small saline contrast in the left atrium; however, these bubbles are typically smaller than those that transit across

an intracardiac shunt, and usually appear late after injection (after >7-10 beats) and persist after the right side of heart empties of contrast saline, representing the typical transit time of the contrast saline through the pulmonary bed and the AVM into the pulmonary veins. An example of saline contrast echocardiography with a right-to-left interatrial shunt is shown in [Figure 8.3](#).

CONTRAST FOR LEFT VENTRICULAR OPACIFICATION

Commercially available contrast agents, specifically formulated to pass through the pulmonary capillary bed, can be used to opacify intracardiac chambers in order to enhance endocardial border definition. When activated, contrast agents yield perfluorocarbon microbubbles encapsulated in either a lipid or albumin shell, which exhibit lower acoustic impedance than blood and enhance the intrinsic backscatter of blood.⁹ The most important clinical use of contrast agents in critical care is for left ventricular opacification (LVO), to be used when standard TTE images are suboptimal, which occurs in 25% or more of cases in the critical care setting.¹⁰ These agents are useful in improving image quality in technically difficult echocardiograms and can provide significant additional diagnostic information, especially on LV function, the presence of LV apical thrombus, and detection of LV wall motion abnormalities.¹¹ Importantly, contrast for LVO has also been shown to reduce the need for other, more involved imaging modalities in the critical care population, such as TEE.¹²⁻¹⁴ An example of contrast used for LVO in a patient with technically difficult echo windows is shown in [Figure 8.4](#). In patients in whom contrast for LVO is used, the enhanced Doppler signals with the use of contrast can also be utilized for detection and measurement of faint tricuspid regurgitation (TR) signals for the estimation of pulmonary artery (PA) pressure, especially important in the critical care scenario.¹⁰

Figure 8.3 Young patient with hypoxia who had a saline contrast injection to rule out patent foramen ovale. **A**, Saline (*) enters right side of heart. **B**, Left side of heart opacifies with saline. LA, left atrium; LV, left ventricle; RA, right atrium.

Figure 8.4 Apical four-chamber view with contrast enhancement demonstrating akinetic left ventricular apex during systole. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

HANDHELD ECHOCARDIOGRAPHY

Handheld ultrasound devices are small, highly portable devices that can now be held in the palm of a hand. They can provide reasonable 2D and color Doppler images, have been shown to correlate reasonably well with full echocardiographic platforms, and detect clinically relevant findings.¹⁵ Early concerns that unskilled users would obtain and subsequently misinterpret poor quality data have largely been ameliorated, and several reasonable studies suggest that noncardiology trained intensivists can successfully perform and correctly interpret a goal-directed transthoracic echocardiogram with a handheld device.^{16,17} “Goal-directed” 2D imaging is typically limited to the assessment of biventricular size and function, and presence or absence of pericardial effusion. As handheld devices are technically

adequate to evaluate major cardiac disease or trauma, a focused 2D study done by a trained individual with only a handheld device has great potential for rapid triage of patients in the emergency room or the intensive care area.¹⁸⁻²³ It is important to emphasize that unclear or ambiguous findings on handheld examination should be followed by a full study on a full echocardiographic platform to obtain accurate diagnosis; in addition, full Doppler interrogation for accurate detection of valve stenosis/regurgitation and accurate hemodynamic evaluation in suspected tamponade warrant comprehensive echocardiography on full-platform machines.

INDICATIONS FOR ECHOCARDIOGRAPHY

Although a broad range of critically ill patients are candidates for TTE to assess cardiac pathology and function, specific indications are summarized in [Box 8.1](#). In general, any critical care patient with unexplained hypotension, pulmonary congestion, hemodynamic instability, known cardiac disease, a significant unexplained cardiac murmur, thoracic trauma, or suspected endocarditis are candidates for echocardiography. The most common use of TEE in critical care is inadequate or nondiagnostic TTE. [Box 8.2](#) lists the major indications for use of TEE in critical care.

ASSESSMENT OF LEFT VENTRICULAR FUNCTION

SYSTOLIC FUNCTION

Although there are a variety of methods to assess LV systolic function by echocardiography (Doppler calculation of stroke volume, dP/dt using mitral regurgitation [MR] signal, tissue Doppler systolic velocity, and systolic strain and strain rate), the most commonly used and clinically relevant is the calculation or estimation of LV ejection fraction (EF).^{24,25} As recommended in current guidelines,²⁴

Box 8.1 Indications for Transthoracic Echocardiography in Critical Care

Hemodynamics

Left ventricular function
 Regional wall motion abnormalities

Bacterial endocarditis

Trauma

Blunt thoracic trauma
 Penetrating thoracic trauma

General

Assess proximal ascending aorta—dissection, hematoma
 Source of murmur
 Source of embolus
 Procedural guidance (especially pericardiocentesis)

Box 8.2 Indications for Transesophageal Echocardiography in Critical Care

Inadequate or nondiagnostic transthoracic echocardiographic images
 Evaluate suspected aortic dissection or trauma
 Evaluate prosthetic valves, especially mitral
 Investigate persistent hypoxemia
 Detect presence of valvular vegetations
 Identify complications of infective endocarditis:
 Abscesses
 Leaflet perforation
 Pseudoaneurysm formation
 Fistulas
 Identify cardiac source of systemic embolus:
 Thrombus in left atrium and left atrial appendage
 Patent foramen ovale/atrial septal aneurysm
 Atheromatous debris of the aorta
 Identify pulmonary embolus in transit
 Characterize intracardiac shunts:
 Atrial septal defect (ASD)
 Ventricular septal defect (VSD)
 Anomalous pulmonary venous connections
 Guide invasive procedures:
 Shunt closure
 Percutaneous balloon valvuloplasty

Table 8.1 Grading Left Ventricular Systolic Function by Left Ventricular Ejection Fraction

Systolic Function	Ejection Fraction
Hyperdynamic	>70%
Normal	55-70%
Mildly depressed	45-54%
Moderately depressed	30-44%
Severely depressed	<30%

calculation of left ventricular ejection fraction (LVEF) by method of discs (Fig. 8.5) is recommended, although visual estimation of LVEF is reliable when technically adequate images are evaluated by experienced echocardiographers.²⁶ EF (end-diastolic volume – end-systolic volume/end-diastolic volume) is dependent not only on intrinsic contractility but also on LV preload and afterload. Therefore, both factors should be considered when assessing LV systolic function. In general, LV systolic function is hyperdynamic when LVEF is greater than 70%, normal at 55% to 70%, mildly depressed at 45% to 54%, moderately depressed at 30% to 44%, and severely depressed at less than 30% (Table 8.1).²⁴ In the presence of regional dysfunction, EF

from multiple views should be integrated to accurately assess LV systolic function. To improve the accuracy of EF calculation by echocardiography, it is essential to avoid foreshortened apical views and to use intravenous contrast material when needed to enhance endocardial border definition (see Fig. 8.4). Aside from measurements of systolic function, 2D echocardiography is of great use in reliably assessing LV dimensions, wall thickness, volumes, and mass.²⁴ Reliable assessments of LV dimensions and EF, particularly when combined with knowledge of filling pressures, can be used to guide and assess the response to therapeutic measures of volume infusion or intravenous administration of inotropic/vasodilator or vasopressor drugs.

TDI-derived myocardial velocities (Fig. 8.6) have been utilized to assess global LV systolic properties.²⁷ This approach is dependent on TD technology to record mitral annulus and myocardial signals, which can be acquired from any area of the heart. However, because of their dependence on Doppler principles, they are of limited value when proper alignment cannot be achieved between the ultrasound beam and the plane of cardiac motion. TDI measurements of systolic annular velocity have been shown to reflect systolic dysfunction, even in the presence of normal LVEF (such as in hypertrophic cardiomyopathy [HCM] or infiltrative cardiomyopathy [ICM]).²⁷⁻²⁹ Using speckle tracking imaging, a 2D echocardiographic technique that measures myocardial motion over time, myocardial deformation (strain) and rate of deformation (strain rate) can also be used to assess LV systolic function.^{30,31} As in TDI, strain and strain rate can detect significant myocardial systolic abnormalities, even in the presence of preserved LVEF.^{32,33} As with TDI, this is of particular importance in patients with diastolic heart failure, hypertensive heart disease, HCM, and

infiltrative disease, when normal EF can coexist with significant and clinically important abnormalities of systolic function.

DIASTOLIC DYSFUNCTION

LV diastolic dysfunction in the intensive care unit (ICU) may be present as a result of cardiac as well as systemic disorders that can affect cardiac function: coronary and hypertensive heart disease, diabetes mellitus, amyloidosis, and HCM. A careful assessment of LV diastolic function by echocardiography can contribute essential information for the management of these patients.³⁴⁻³⁶ In general, LV diastolic function refers to LV relaxation (measured as the rate of decay of LV systolic pressure during the isovolumic relaxation period) and LV chamber stiffness. In turn, chamber stiffness is calculated using measurements of LV volume and pressure during the diastolic filling period. However, prediction of LV filling pressures integrates the effects of the preceding hemodynamic variables as well as other factors such as RV filling, pericardial constraint, and LA function on LV diastolic function.

The recommended clinical approach for the assessment of LV diastolic function (European Association of Echocardiography [ASE] guideline algorithms) begins with the 2D examination to determine LV dimensions and volumes and the presence and extent of LV hypertrophy, using standard ASE criteria (Figs. 8.7 and 8.8).³⁷ Patients with a depressed EF or LV hypertrophy have impaired LV relaxation. Therefore, even in the absence of any corroborating Doppler information, one can still conclude that LV relaxation is impaired in these patients. Furthermore, this information

can be combined with the mitral inflow pattern to predict filling pressures. It is also important to measure left atrial (LA) volume using apical four- and two-chamber views because LA volume is related to the extent of diastolic dysfunction when increase in LA volume parallels deterioration of LV diastolic function.³⁸ Mitral inflow is obtained using pulse Doppler, with a 1- to 2-mm sample volume placed at the level of mitral valve tips.³⁹ Early diastolic flow and velocity (E) occur in response to a positive pressure gradient between the LA and the LV, resulting from a rapidly decreasing LV pressure due to LV relaxation and early diastolic suction. In late diastole, LA contraction leads to another positive pressure gradient and late diastolic flow or the A velocity. With normal LV relaxation, early diastolic flow predominates and the E/A ratio is greater than 1. However, when LV relaxation is impaired, LV diastolic pressure is

elevated and a reduced E velocity is observed. This leads to a higher LA preload and contraction velocity. Therefore, the E/A ratio decreases in the presence of impaired LV relaxation. Because LA pressure usually increases to maintain forward stroke volume, early diastolic transmitral pressure gradient increases, leading to a higher E velocity and E/A ratio. Because of the simulation to normal mitral inflow, this pattern is referred to as a pseudonormal mitral inflow pattern. In more advanced disease with markedly elevated LA pressure, the E velocity increases even further, resulting in a “restrictive” inflow pattern, in which E/A ratio is 2 or greater. It is possible to unmask the presence of impaired LV relaxation in these cases by performing a Valsalva maneuver. The decrease in venous return during the strain phase of Valsalva results in a decrease in LA pressure and E/A ratio.⁴⁰⁻⁴² TD-derived early diastolic mitral annular velocity (e') can be recorded by pulsed Doppler at mitral annulus. When combined with E, E/ e' ratio is obtained, which has been shown to be a reasonable correlate of LV filling pressure,⁴¹ although multiple diastolic echo-Doppler variables need to be synthesized to result in an accurate assessment of LV diastolic function.⁴³⁻⁴⁵

Pulmonary venous (PV) flow can also be analyzed to predict LV filling pressures. PV flow signals are readily recorded in the majority of patients seen in the outpatient laboratory but can be challenging in the critical care setting. Antegrade forward flow from the pulmonary vein into the left atrium occurs during systole (S) and early and mid-diastole (D). After atrial contraction, retrograde flow (Ar) from the left atrium into the pulmonary vein occurs. At the earlier stages of diastolic dysfunction where LV end-diastolic pressure is increased, the peak velocity and duration of Ar (velocity > 30 cm/second and Ar-A duration ≥ 35 ms) become more prominent.^{42,46} Subsequently, with the rise in mean LA pressure, antegrade systolic flow decreases, whereas the D velocity increases with a shortening of its deceleration time. Assessment of PA systolic and diastolic pressures (see later) can provide helpful corroborating

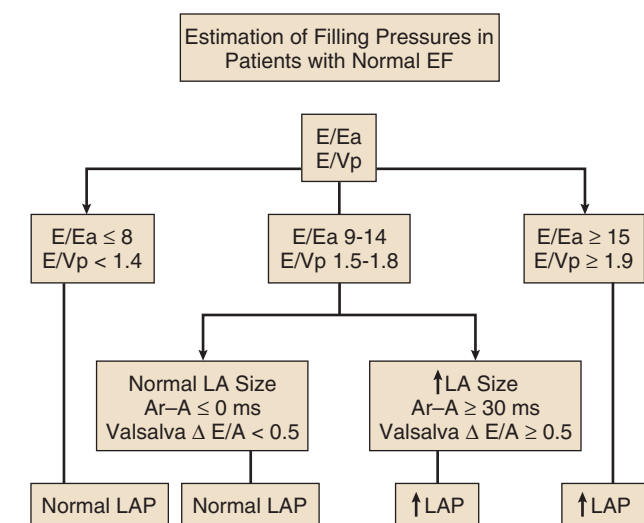

Figure 8.7 Algorithm for estimation of left ventricular filling pressures with normal ejection fraction.

evidence of the status of LV filling pressures. In the absence of pulmonary parenchymal and vascular disease, and in the presence of significant cardiac valvular disease or cardiomyopathy, one can reasonably infer that PA pressures are increased due to an elevated LA pressure. **Figure 8.9** shows an example of a patient with preserved LVEF with elevated LV filling pressures as assessed by integrated diastolic assessment with multiple echo-Doppler variables.

ISCHEMIA/INFARCTION INCLUDING COMPLICATIONS

Echocardiography is essential for the assessment of LV regional function in the critical care setting when the diagnosis of ischemia/infarction is entertained. Adequate images, particularly when combined with harmonics and intravenous contrast, can provide comparable information to that obtained by TEE.^{12,13} Furthermore, serial assessment of regional function is possible after the administration of thrombolytic drugs or percutaneous revascularization. In addition to technically good images, interpretation by an experienced echocardiographer is essential for achieving high accuracy. Regional function is determined by examining endocardial motion as well as local thickening. Abnormal LV regional function is usually determined when the dysfunction is observed in more than one plane, with particular LV segments corresponding to specific coronary artery distributions. An echocardiographic regional map for the identification of wall motion abnormalities and their correlation to coronary anatomy is shown in **Figure 8.10**. In general, thin (<5 mm in diameter), bright myocardial walls with abnormal motion are indicative of scars [?] (**Fig. 8.11**).

When there is a wall with thin walls that moves opposite to adjacent, normal walls (“bulging”), aneurysm is often the cause (**Fig. 8.12**); in this case, thrombus in the aneurysm must be excluded to prevent systemic embolism. In addition to epicardial coronary artery disease, myocarditis, dilated cardiomyopathy (DCM), and abnormal conduction patterns (particularly RV pacing and left bundle branch block) can result in regional dysfunction. Therefore, final conclusions regarding cause of wall motion abnormalities should be made only after integration of clinical findings including electrocardiogram (ECG). In the setting of acute myocardial infarction, a number of studies have substantiated the prognostic power of echocardiography, particularly LVEF, LV diastolic function, RV function, and significant valve dysfunction.⁴⁷ Regional function is most reflective of long-term outcome when imaging is performed after recovery of myocardial stunning (usually a week to 10 days after presentation). However, in the acute setting, echocardiography may be obtained to help establish the diagnosis of an acute ischemic syndrome, determine the extent of myocardium at risk, identify apical clots (**Fig. 8.13**), and detect the presence of mechanical complications such as ventricular septal defect (VSD) (**Fig. 8.14**), contained cardiac rupture called pseudoaneurysms (**Figs. 8.15** and **8.16**), MR, pericardial effusion, and RV infarction, all of which may require urgent intervention.⁴⁸

CARDIOMYOPATHY

HYPERTROPHIC CARDIOMYOPATHY

HCM is an inherited disorder that is characterized by unexplained LV hypertrophy in the absence of longstanding

ECHOCARDIOGRAPHIC REGIONAL FUNCTION AND CORONARY ARTERY DISTRIBUTION

hypertension or infiltrative disease.⁴⁹ At the pathologic level, there is myocyte disarray, with replacement of healthy myocytes with fibrosis. Therefore, on echocardiography, thick LV walls with elevated LV mass are seen. Early in the disease, LV function is usually hyperdynamic, although late in the disease, LVEF can become depressed (“burned-out HCM”). There are various morphologic types of HCM, including septal hypertrophy (Fig. 8.17), concentric (uniform) hypertrophy, apical hypertrophy, and hypertrophy concentrated in LV walls other than the septum. It is important to understand that LV obstruction with resultant dynamic gradients can occur in any of these morphologic types, thus the differentiation between obstructive and nonobstructive HCM. Echocardiography is uniquely positioned to differentiate these morphologic types, determine LV systolic function, assess for left ventricular outflow tract (LVOT) obstruction, identify associated MR, and determine LV filling pressures and PA pressure.⁵⁰ Obstruction in HCM is most often caused

by systolic anterior motion (SAM) of the mitral valve (Fig. 8.18), which physically obstructs the LVOT, resulting in a significant gradient. From the clinical point of view, HCM patients can present to critical care with hypotension, congestive heart failure, arrhythmias, stroke, and cardiac arrest; echocardiography is crucial in differentiating the underlying disease state and functional/morphologic associations with these presentations.

DILATED CARDIOMYOPATHY

DCM refers to nonischemic global LV systolic dysfunction often associated with RV dysfunction. Although viral myocarditis can cause this same picture, in general, DCM refers to familial inherited cardiomyopathy but can be caused by a variety of conditions including alcohol abuse,

chemotherapeutic agents, and endocrine disorders. As genetic methods for diagnosing inherited DCM become more refined, an increasing proportion of idiopathic nonischemic cardiomyopathy is found to be inherited.⁵¹ From the echocardiographic standpoint, DCM is readily diagnosed by dilated LV with depressed EF and often RV dysfunction; for final diagnosis, exclusion of a sufficient degree of coronary artery disease to explain degree of LV dysfunction is necessary.⁵² Secondary MR and TR can be seen by color and spectral Doppler interrogation, and LV filling pressure and PA pressure assessments are important in clinical management. An example of a patient with DCM is seen in Figure 8.19.

INFILTRATIVE/RESTRICTIVE CARDIOMYOPATHY

ICMs are characterized by the deposition of abnormal substances that cause the ventricular walls to become progressively rigid, thereby impeding ventricular filling.⁵³ This impedance to normal LV filling is termed “restrictive filling;” hence the other name, “restrictive cardiomyopathy.” However, because any cardiomyopathic process can have restrictive filling (ischemic, dilated, hypertrophic), the preferred term is ICM. Some ICMs can cause LV and RV thickening, such as the archetypal ICM cardiac amyloidosis (Fig. 8.20), although others can cause ventricular thinning, such as sarcoidosis. From the echocardiographic point of view, thickened ventricular walls with restrictive LV filling and at time depressed LVEF are seen in amyloidosis;⁵⁴ the differentiation from HCM and hypertensive heart disease is made by the presence of low ECG voltages in ICM, as normal myocytes are replaced by amyloid. For sarcoidosis, many LV patterns can be seen, but focal LV aneurysms are typical; heart block on ECG is also often seen.

ASSESSMENT OF RIGHT VENTRICULAR FUNCTION

Echocardiographic assessment of RV function is challenging because of its complex shape. However, it is possible to integrate information from multiple views to reach reasonably accurate conclusions on RV size and function. In the parasternal short-axis view, the RV appears crescent-shaped, whereas in the apical four-chamber view it is triangular with its base along the tricuspid valve. Visually, assessment of RV size is usually done by comparing RV and LV transverse dimensions in the parasternal short-axis (Fig. 8.21) and apical views (Fig. 8.22). In general, the RV dimensions are one third of the LV dimensions. As the right ventricle dilates, its free wall bulges and in patients with moderate enlargement, RV dimensions are almost equal to those of the left ventricle. RV size is larger than LV size in patients with severe enlargement, with the right ventricle forming the cardiac apex. It is possible to measure RV end-diastolic and end-systolic dimensions and area in the apical four-chamber view; however, caution should be exercised to avoid tangential and foreshortened views. Normal RV

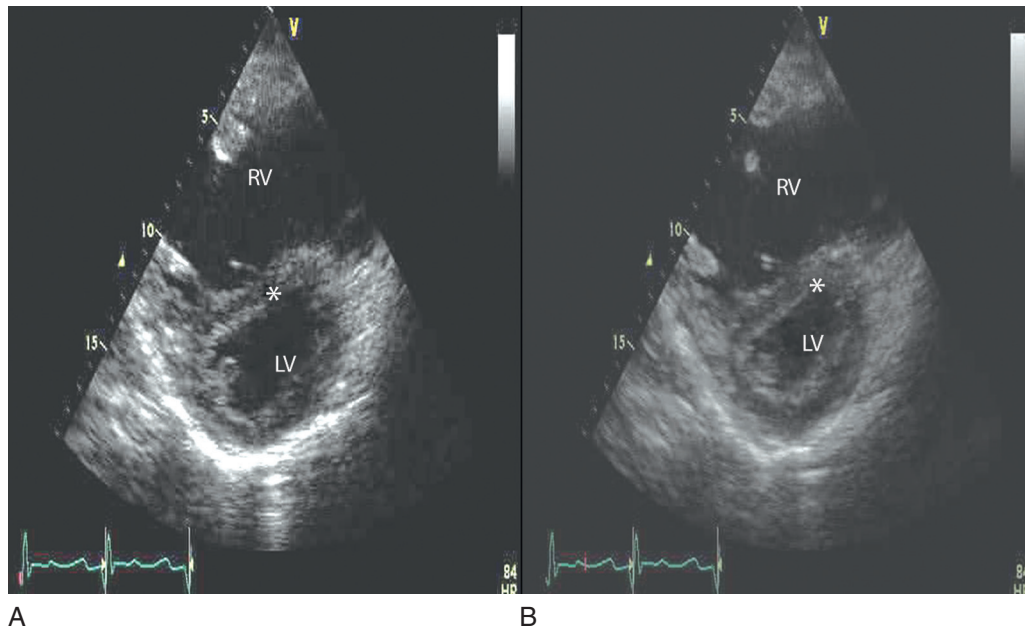

Figure 8.21 Short-axis view of “D-shaped” left ventricle in systole (**A**) and diastole (**B**) with marked right ventricular enlargement. LV, left ventricle; RV, right ventricle.

Figure 8.22 Apical four-chamber view of marked right ventricular dilatation. LV, left ventricle; RA, right atrium; RV, right ventricle.

dimension at the tricuspid annular level in the apical four-chamber view is less than 4.1 cm.⁵⁵ RV wall thickness is normally less than 0.5 cm and is most reliably measured by 2D echocardiography in subcostal views at the level of the tricuspid valve chordae tendinae.⁵⁵ If needed, contrast enhancement may be used. During TEE, RV size can be assessed in the midesophageal four-chamber view.

RV systolic function is estimated qualitatively in clinical practice as normal or mildly, moderately, or severely depressed function. It is also possible to obtain a quantitative measurement of RV systolic function by measuring RV fractional area change (FAC = end-diastolic area – end-systolic area/end-diastolic area) in the apical four-chamber view. This is a simple method with reasonable reproducibility and accuracy, and its normal value ranges to greater than 35%.⁵⁵ RV Tei index (TR duration – duration of systolic flow

through the RV outflow tract/duration of systolic flow through the RV outflow tract) can be calculated as well, but it provides a combined assessment of RV systolic and diastolic function and is prone to various measurement errors.⁵⁶ The tricuspid annulus motion can provide useful information in patients with suboptimal visualization of RV free wall; normal tricuspid annular plane systolic excursion (TAPSE) is greater than 1.6 cm.⁵⁵ Additional information may be obtained by TD-derived tricuspid annulus systolic velocity.^{57,58} Strain and strain rate⁵⁹ measurements have been applied in a number of diseases that affect the right ventricle, such as congenital heart disease, pulmonary embolism, and idiopathic pulmonary hypertension, and can indicate RV systolic abnormalities even in the presence of normal visual RV function, TAPSE, or FAC. Their routine clinical application, however, awaits additional improvements in the technique to enhance its reproducibility and to show the incremental information provided over 2D imaging and myocardial velocities.

Conditions of RV volume overload (e.g., ASD, severe TR or pulmonary regurgitation) result in diastolic flattening of the interventricular septum, which becomes rounded in systole, but RV pressure overload (primary pulmonary hypertension, acute or chronic thromboembolic disease, cor pulmonale) results in systolic and diastolic flattening of the interventricular septum (“D-shaped ventricle” in systole and diastole; see Fig. 8.21).⁶⁰ Acute RV dilatation can reduce LV filling through an increase in intrapericardial pressure, which in turn reduces LV transmural filling pressure.⁶¹ An acute decline in RV function is usually accompanied by RV dilatation and decrease in RV systolic function in the presence of normal wall thickness. In the setting of an acute coronary syndrome, this may happen as a result of RV ischemia or infarction. The presence of normal/reduced PA pressures along with regional dysfunction can help identify these patients. Patients with chronic RV pressure overload (for example, idiopathic pulmonary hypertension) often

Table 8.2 Echocardiographic Assessment of Aortic Regurgitation Severity

Finding	Mild	Moderate	Severe
Central jets: color jet width/LVOT diameter	<25%	25-64%	≥65%

LV, left ventricle; LVOT, left ventricular outflow tract.

exhibit a dilated right ventricle with reduced contractility and increased wall thickness (see Fig. 8.22) in the presence of increased PA pressures and vascular resistance.⁶²

DETERMINING VALVULAR FUNCTION AND DYSFUNCTION

Echocardiography provides important anatomic and physiologic information on cardiac valves. Valve morphologic features can be reliably assessed using 2D imaging. For example, the presence of thickening and calcification of aortic valves and the presence of prolapse/flail or rheumatic deformity of the mitral valve can be readily identified. Importantly, secondary changes such as chamber enlargement and LV/RV function can be followed serially, thus enabling timely decisions with respect to surgery or percutaneous interventions. Using 2D images and Doppler, it is possible to assess the severity of valvular stenosis or regurgitation and to calculate PA pressures.

EVALUATION OF MITRAL, TRICUSPID, AND AORTIC REGURGITATION

Similar principles apply to the assessment of mitral (MR), tricuspid (TR), and aortic (AR) regurgitation. Pulsed, CW, and color Doppler are useful, when combined, in identifying and accurately grading AR (Table 8.2), MR (Table 8.3), and TR (Table 8.4).⁶³ Echocardiographic assessment of regurgitant valves includes the 2D and comprehensive Doppler imaging in multiple views to identify the direction and size of regurgitant jets. Color Doppler has reasonable accuracy in assessing the severity of MR, TR, or AR when jets are central, although the severity of eccentric jets can be underestimated. In addition, several technical and physiologic factors can affect the size of the jet, irrespective of regurgitant volume, including color gain, pulse repetition frequency, filter settings, and atrial (or aortic)/ventricular pressures. Therefore, it is important to record blood pressures at the time of echocardiography. For MR and TR, the ratio of the jet area to LA or RA area has been used in clinical and research studies to assess these lesions; it

Table 8.3 Echocardiographic Assessment of Mitral Regurgitation Severity

Finding	Mild	Moderate	Severe

is important that the Nyquist limit for color Doppler be greater than 55 cm/second for accurate assessment. For AR, the width of the jet at its origin is related to that of the LVOT to arrive at the ratio that expresses the severity of AR. It is also possible to measure the cross-sectional area of the regurgitant jet by planimetry and relate that to the corresponding area of the LVOT in the short-axis views. Figure 8.23 shows an image of severe MR, Figure 8.24 demonstrates significant posteriorly directed AR, and Figure 8.25 shows severe TR.

Figure 8.23 Apical four-chamber view demonstrating severe mitral regurgitation (*right panel*). LA, left atrium; LV, left ventricle.

Figure 8.24 Long-axis view demonstrating severe posteriorly directed aortic regurgitation. LA, left atrium; LV, left ventricle; MV, mitral valve.

The “vena contracta” of the regurgitant jet, defined as the narrowest area of the jet that occurs at the orifice,⁶⁴ can be readily imaged and measured. As the regurgitant volume increases, vena contracta width increases (**Fig. 8.26**). The flow convergence method (proximal isovelocity surface area, or PISA, method) is a quantitative approach that can measure the regurgitant volume and the effective regurgitant orifice (ERO) area. Color flow mapping enables the visualization of the concentric hemispheres of flow as they approach the ERO (**Fig. 8.27**). The ERO area is calculated as:

$$6.28 \times r^2 \times V_a / V_{\text{peak}}$$

where V_a is the aliasing velocity, r is the maximal radius of the PISA, and V_{peak} is the peak velocity of the regurgitant signal by CW Doppler⁶⁵ (**Fig. 8.27**). This method is most reliable when jets are centrally located and the regurgitant orifice is adequately visualized.

The CW signal can provide useful information, as the brightness of these signals—in comparison with antegrade flow—increases with increasing severity of regurgitation. For patients with MR or TR who have severe lesions and a rapid rise in LA or RA pressure resulting in a large regurgitant “V” wave, early systolic peaking is seen (see **Fig. 8.25**,

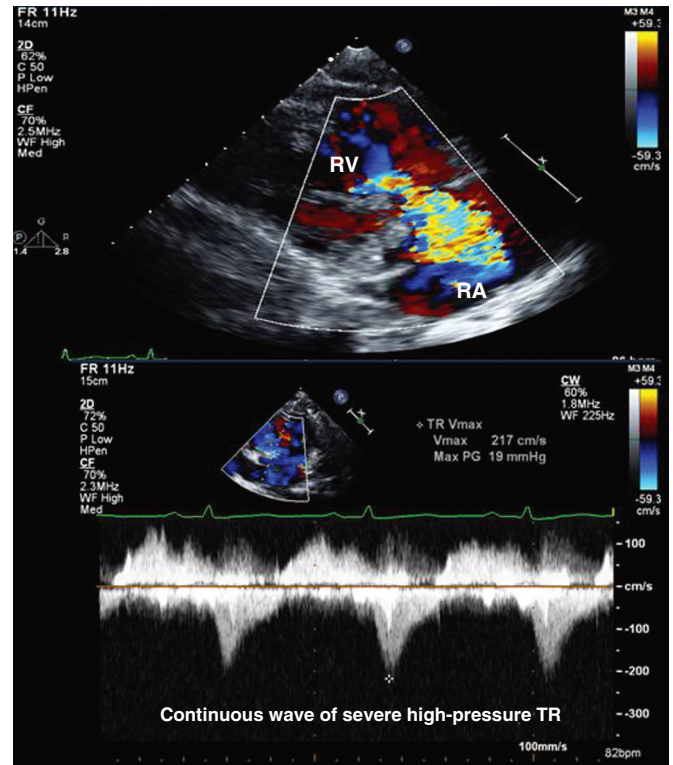

Figure 8.25 Severe tricuspid regurgitation (TR) (*upper panel*). Continuous wave Doppler demonstrating early peaking, low-velocity signal consistent with high right atrial pressure and severe TR (*lower panel*). RA, right atrium; RV, right ventricle.

lower panel). For AR, the deceleration time (pressure half-time = $0.29 \times$ deceleration time) of the AR spectral Doppler signal is related to the rate at which aortic and LV pressures equilibrate in diastole, such that patients with hemodynamically significant lesions exhibit a rapid rise in LV diastolic pressure, leading to steep deceleration of AR velocity signal. In general, severe AR correlates with pressure half-time less than 250 ms, and mild AR with pressure half-time greater than 500 ms.⁶³ The pressure half-time is most reliable in cases with acute AR and may be prolonged in patients with chronic severe AR due to a concomitant increase in LV compliance (**Fig. 8.28**). For MR and TR, peak early diastolic filling velocity by PW (peak E-velocity) is increased in the setting of significant regurgitation because of the increased transvalvular flow generated by the regurgitant volume; in severe MR, a peak E velocity greater than 1.2 m/second is usually present. In addition, pulmonary and hepatic venous flow will show systolic reversal of flow in severe MR or TR, respectively, corresponding to the large regurgitant “V” wave in atrial pressure. In hemodynamically significant AR, diastolic flow reversal is noticed in the descending aorta. Normally, no (or only a minimal amount) flow reversal is seen in the descending aorta in early diastole. In patients with severe AR, holodiastolic flow reversal is observed.

In arriving at final conclusions, it is important to integrate all the findings obtained by 2D and Doppler.⁶³ For example, patients with chronic severe regurgitant lesions usually have dilatation of their cardiac chambers (for MR, LA and LV; for TR, right atrial [RA] and RV; for AR: LV) along with a large regurgitant volume. If the quality of the transthoracic

Figure 8.26 Vena contracta measurements (arrows) of mild (A) and severe (B) mitral regurgitation. LA, left atrium; LV, left ventricle.

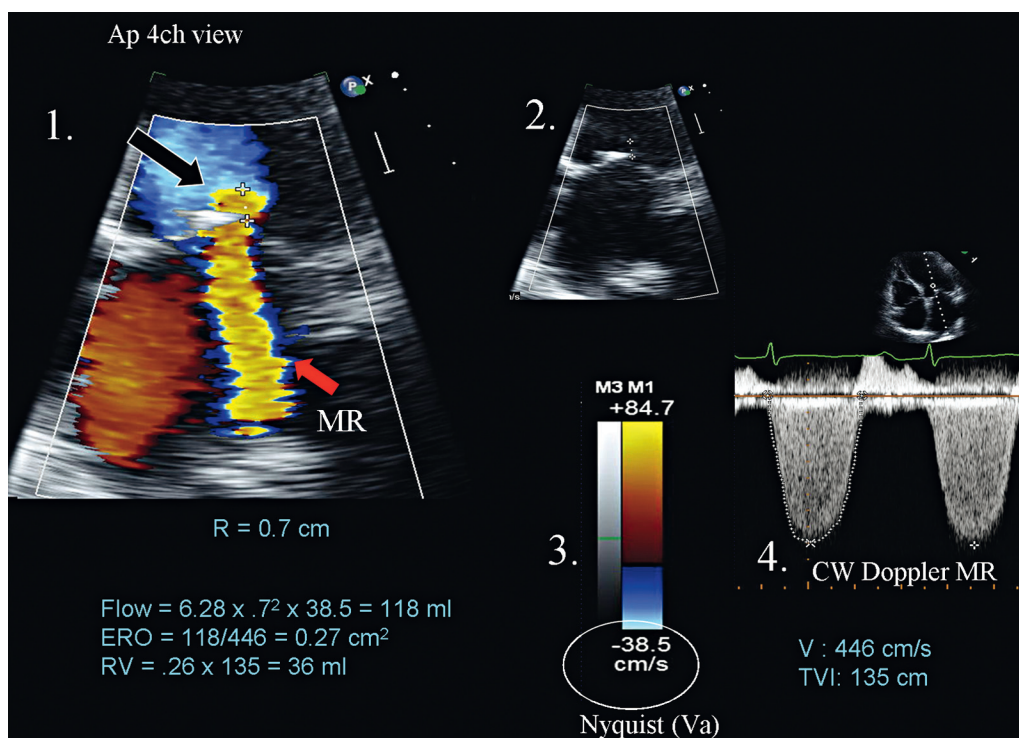

Figure 8.27 Moderate mitral regurgitation (MR) as calculated by the proximal isovelocity surface area method. 1, Isolation and measurement of proximal color radius (black arrow). 2, Confirmation of caliper placement without color. 3, Nyquist (Va) velocity. 4, Continuous wave (CW) Doppler of MR velocity and time velocity integral (TVI). Red arrow, MR jet.

images precludes the assessment of valvular disease, or the severity of MR or AR, it is reasonable to proceed to TEE. All of the preceding methods can be applied for the quantification of regurgitant lesions imaged by TEE. However, with respect to MR assessment by TEE, given the proximity of the TEE probe to the left atrium, MR jet area can be larger than that acquired by transthoracic imaging. In addition, TEE

can provide unique information that is essential for successful mitral valve repair.

EVALUATION OF AORTIC STENOSIS

Patients with aortic stenosis (AS) have abnormally thickened or calcified valve leaflets along with reduced leaflet excursion, as seen by 2D echocardiography (Fig. 8.29).⁶⁶ In

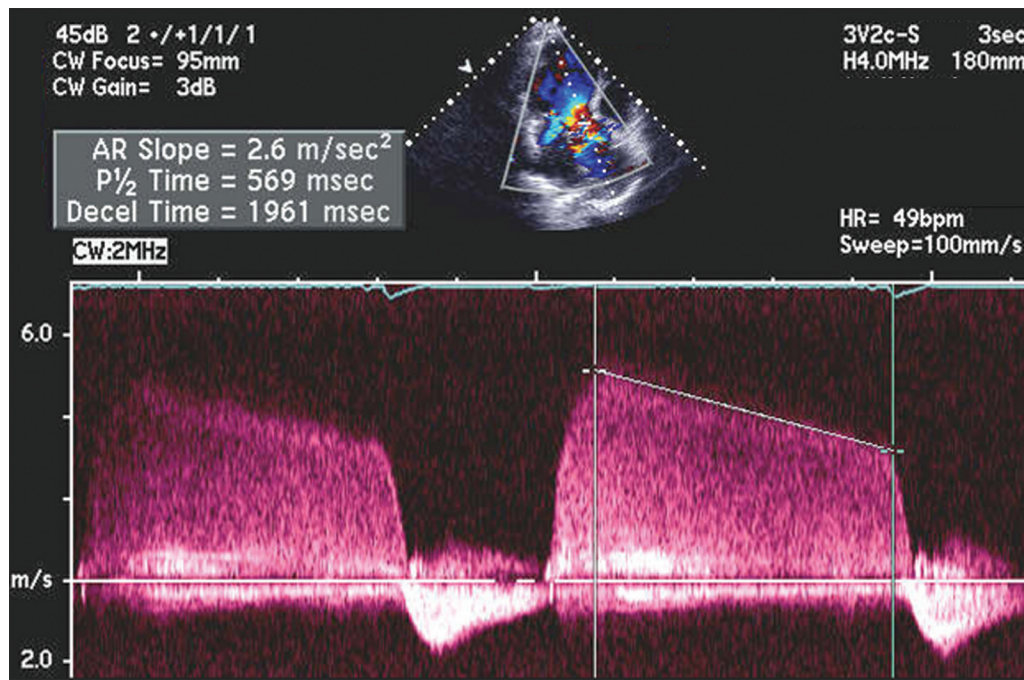

Figure 8.28 Example of online measurement of pressure half-time ($P_{1/2}$ time) of the continuous wave spectral Doppler of aortic regurgitation.

Figure 8.29 Two-dimensional image of calcific aortic stenosis (arrow). LA, left atrium; LV, left ventricle.

patients older than 70 years of age, the most common cause is degeneration of a trileaflet valve, although in patients younger than 70 years old, the most common cause is bicuspid aortic valve. In addition to morphologic changes of the aortic valve, 2D imaging is needed to determine LV dimensions, wall thickness, and EF. Such data are essential to assess the impact of AS on LV function, which is needed as part of the routine evaluation of patients with this disease. AS severity is assessed most reliably by the mean transvalvular systolic pressure gradient across the aortic valve and by the valve area, both of which are measured by Doppler echocardiography. Using the modified Bernoulli equation ($\Delta P = 4v^2$), the peak and mean gradients across the aortic valve can be calculated from the CW Doppler signal. An excellent correlation was observed between invasive and Doppler measurements of mean gradient when both

measurements were simultaneously obtained.⁶⁷ However, several technical requirements are needed, including parallel alignment of the ultrasound beam with aortic flow and the use of multiple imaging windows (apical, right parasternal, subcostal, and suprasternal). Patients with a mild degree of AS may develop increased velocity and gradient when the transvalvular flow rate is increased, whether because of AR or the development of a hyperdynamic state; however, in this case the valve area will reflect the mild severity. Likewise, patients with severe AS may have lower than expected gradients with significantly depressed EF (Fig. 8.30), severe MR, severe RV dysfunction, severe TR, or intravascular volume depletion; again, in such cases, AV area is very useful to put the gradients in context of the stroke volume.

Aortic valve area is calculated using the continuity equation. The underlying principle is that the amount of blood flow through the LVOT and aortic valve will be the same because they are in continuity.⁶⁸ Aortic valve area (in cm^2) is given by systolic flow through LVOT/time velocity integral (TVI) of AS signal by CW ($\text{LVOT diameter}^2 \times 0.785 \times \text{LVOT TVI}/\text{aortic TVI}$) (see Fig. 8.30). The main source of error in this calculation is in the measurement of the LVOT diameter. However, when there is doubt, and in the absence of other significant valvular lesions, it is possible to use systolic flow through the RV outflow tract or diastolic mitral inflow in the numerator. Alternatively, LV stroke volume measured by 2D echocardiography (difference between end-diastolic and end-systolic volumes) may be used, provided adequate 2D images are present.

Some patients with severely depressed EF have only mildly or modestly elevated transvalvular gradients across the aortic valve, yet significant AS when the valve area is calculated (typically $<1 \text{ cm}^2$, see Fig. 8.30). It is reasonable to proceed to low dose (up to $20 \mu\text{g}/\text{kg}/\text{minute}$) dobutamine echocardiography in these patients to assess not only LV

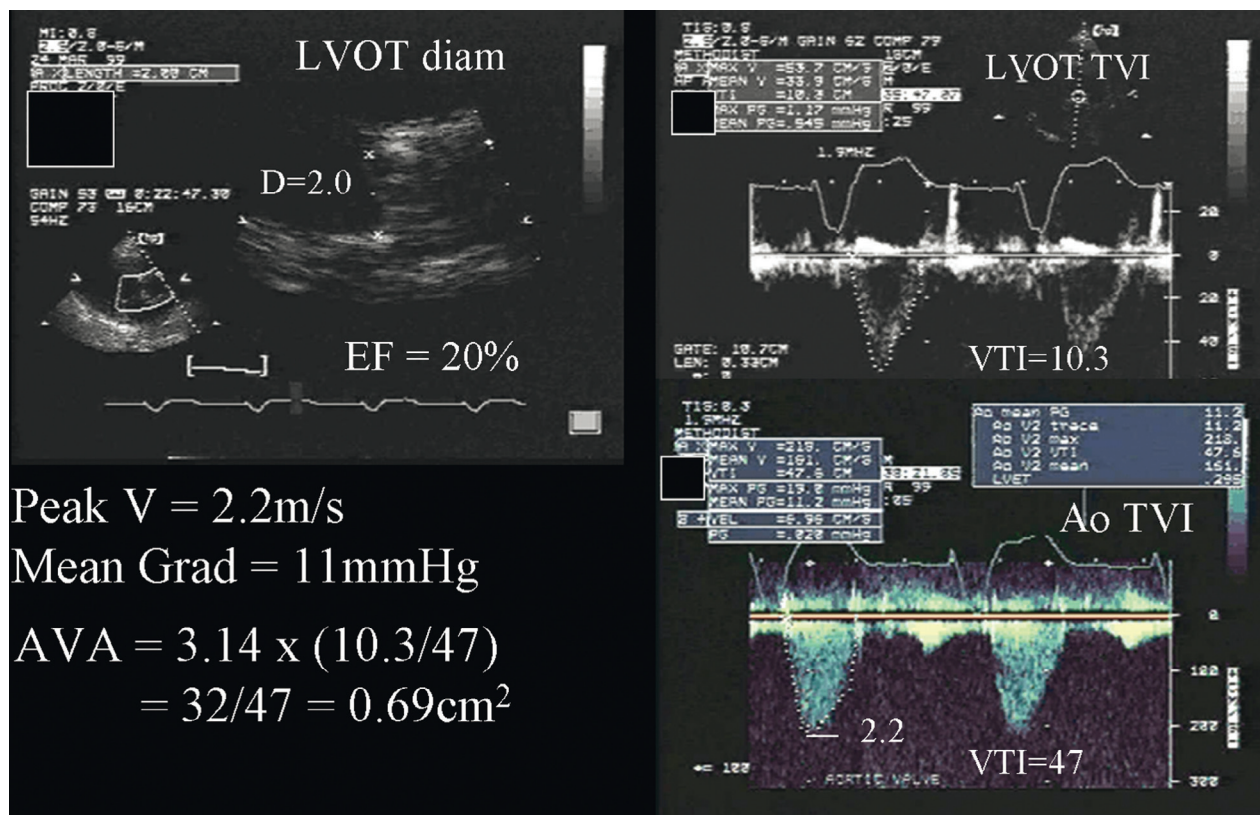

Figure 8.30 Assessment of aortic stenosis in a patient in Class III heart failure. Although the mean gradient is only 11 mm Hg, the calculated valve area is 0.69 cm². In this setting, the use of dobutamine may be efficacious. Ao, aorta; EF, ejection fraction; LVOT, left ventricular outflow tract; TVI, time velocity integral.

Figure 8.31 Long-axis view (*left*) of mitral stenosis demonstrating typical “hockey-stick” appearance of mitral valve. Four-chamber view (*right*) demonstrating doming of anterior leaflet, and marked dilatation of both atria and normal left ventricular and right ventricular size. This patient had rheumatic deformity of both the mitral and tricuspid valves. LA, left atrium; LV, left ventricle; MV, mitral valve; RA, right atrium; RV, right ventricle.

contractile reserve but also the effect of increased transvalvular flow on the calculated aortic valve area.⁶⁹ Patients with dobutamine-induced increase in aortic valve area (>1 cm²) are unlikely to have real AS, but their reduced valve area is largely the result of reduced flow rate. On the other hand, when there is an increase in gradient but still a severely reduced aortic valve area, valvular surgery should be considered because LV function and clinical status are likely to improve after valve replacement.

EVALUATION OF MITRAL STENOSIS

In patients with rheumatic mitral stenosis, 2D imaging shows the presence of valvular thickening and calcification along with abnormal leaflet mobility, such that there is doming of the anterior mitral leaflet along with reduced mobility of the posterior leaflet.⁶⁶ The anterior leaflet has a classic “hockey-stick” deformity when viewed in the parasternal long-axis and apical views (Figs. 8.31), and variable degrees of calcification, thickening, and subvalvular disease may be

present. Direct planimetry of the mitral valve area is feasible in cases in which the mitral valve orifice is well visualized in the parasternal short-axis view. However, this measurement can be inaccurate when there is extensive calcification of valve leaflets, and when the short-axis plane is not positioned correctly at the level of valve tips. Color Doppler shows the PISA hemispheres on the LA side of the mitral valve during diastole (Fig. 8.32). Spectral Doppler can provide reliable transmitral pressure gradients and mitral valve area in most patients with mitral stenosis, as well as the hemodynamic impact on the right side of the heart with development of pulmonary hypertension (see Fig 8.33).

Figure 8.32 Parasternal long-axis view of a stenotic mitral valve demonstrating flow acceleration by color (proximal isovelocity surface area [PISA]) on the atrial side of the valve (arrow). Ao, aorta; LA, left atrium.

The current ultrasound systems have the capability to measure online peak and mean transvalvular gradients, using the modified Bernoulli equation (see earlier). Doppler-derived gradients have been shown to have excellent reproducibility and accuracy when compared to the simultaneously obtained LA-LV pressure gradient by cardiac catheterization. However, the transmitral pressure gradient is dependent on many variables other than the valve area. Therefore, the mean gradient can be increased with high transvalvular flow rate (whether because of a hyperdynamic flow state or MR), or short RR interval, even though mitral stenosis is only of a mild degree.

Mitral valve area is most easily calculated by Doppler, using the pressure half-time method. This method was originally conceived in the cardiac catheterization laboratory.⁷⁰ The severity of the stenosis is judged based on the time needed for the transmitral pressure gradient to decrease by 50% from its initial value in early diastole. This time increases with the severity of the stenosis, and mitral valve area (in cm^2) can be derived as $220/\text{pressure half-time}$ (in ms). Although simple and highly reproducible, its accuracy is limited in patients with abnormal LA or LV compliance, and those with significant AR.⁷¹ The continuity equation is an additional method that is applicable in cases without significant AR and MR. In this method, the mitral valve area is calculated by systolic flow through the LVOT/TVI of mitral stenosis jet by CW.

EVALUATION OF PROSTHETIC VALVES

Echocardiography is the test of choice to assess prosthetic valve function.⁷²⁻⁷⁴ From transthoracic windows, it is possible to identify the type of prosthetic valve, whether tissue or mechanical, the latter producing significant prosthetic

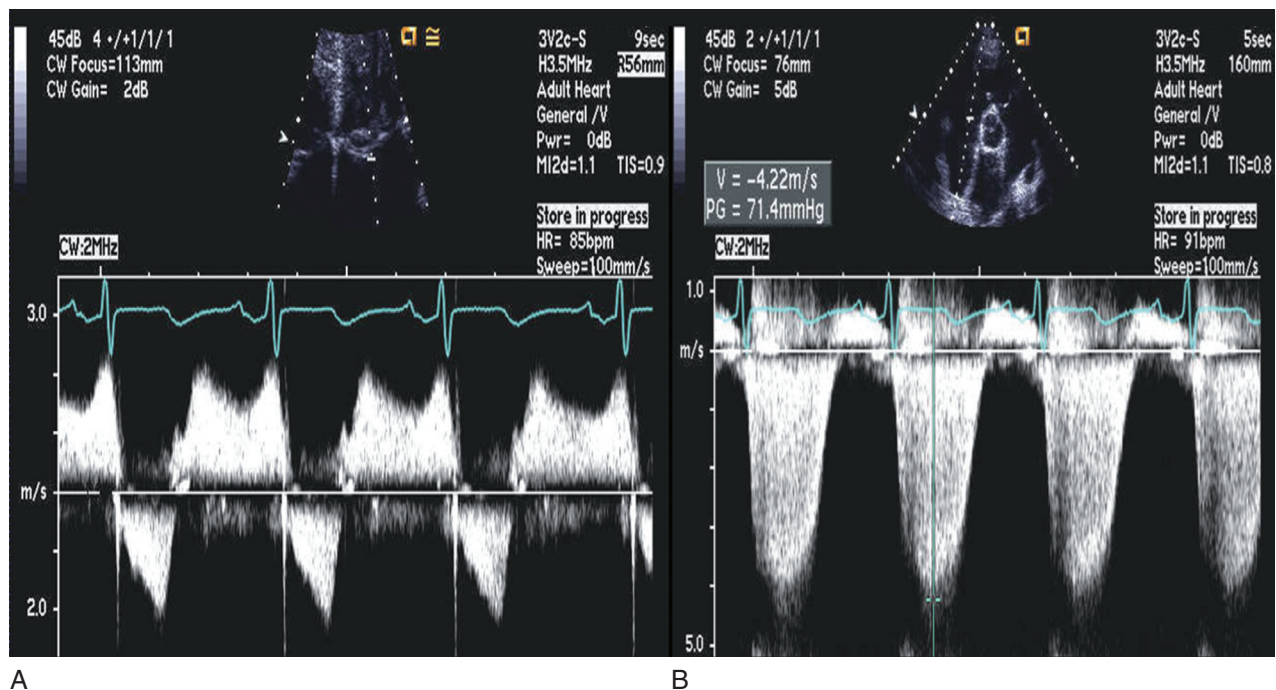

Figure 8.33 **A**, Continuous wave (CW) Doppler display of mitral stenosis. Peak velocity is 2.2 m/second; time velocity integral, 67 cm; mean gradient, 11 mm Hg; mitral valve area, 1.3 cm^2 , at a heart rate of 85 beats per minute. **B**, Tricuspid regurgitant signal from same patient demonstrating secondary pulmonary hypertension and a calculated right ventricular systolic pressure of at least 81 mm Hg, assuming a right atrial pressure of at least 10 mm Hg.

Figure 8.34 Transesophageal echocardiography of mechanical mitral valve open (arrows), demonstrating prosthetic artifact (*). LA, left atrium.

Figure 8.35 Transesophageal echocardiography of mechanical mitral valve when closed demonstrating artifact (*). LA, left atrium; LV, left ventricle.

echo artifact (Figs. 8.34 and 8.35). In some cases, large vegetations (Fig. 8.36) or thrombi may be visualized. However, in many situations of suspected prosthetic valve disease, TEE is needed because TTE images, especially with mechanical valves, can be obscured by echo artifact. Reliable recording of transvalvular gradients is possible by Doppler in almost all cases, provided the ultrasound beam is parallel to the direction of flow. Prosthetic valve gradients should be interpreted with the knowledge of the valve type, size, and position, as values vary depending on these variables (Table 8.5). Furthermore, consideration should be given to stroke volume/ventricular function/heart rate when conclusions are drawn about prosthetic valve function. It is very useful to compare Doppler-derived gradients to previous results (taking into consideration both flow and heart rates) in detecting possible changes in prosthetic valve function over time. For prosthetic aortic valves, the Doppler velocity index is calculated as peak velocity in LVOT/peak velocity across the valve by CW Doppler. Patients with normal function have a ratio that is 0.25 or greater. This ratio is particularly helpful in patients with increased transvalvular flow rate leading to increased mean gradient, as they will

Figure 8.36 Basal short-axis TTE image of a bioprosthetic tricuspid valve with a large vegetation (arrow). The lesion caused both significant obstruction and regurgitation. AO, aorta; RA, right atrium; RV, right ventricle.

Table 8.5 Normal Doppler Values in Patients with Prosthetic Valves

Valve Type	Peak Velocity	Mean Gradient	Doppler Velocity Index
Aortic	≤3 m/sec*	≤25 mm Hg*	≥0.30
Mitral	<1.9 m/sec†	≤5 mm Hg†	
Tricuspid	<1.5 m/sec†	≤3 mm Hg†	
Pulmonary	≤3 m/sec*	≤25 mm Hg*	≥0.30

*Assuming normal stroke volume/ventricular function.

†Assuming normal heart rate (50–70 beats/min).

also have an increased flow velocity in the LVOT and therefore a normal Doppler velocity index.⁷⁵ Prosthetic mitral valves are best assessed by mean gradient, taking into account heart rate, as the faster the heart rate, the higher the gradient. In general, a mean prosthetic mitral gradient at a heart rate of 60 to 70 beats per minute should be less than 5 mm Hg in a normally functioning mitral prosthesis (Fig. 8.37). When there is doubt about structural or functional abnormalities of prosthetic valves, TEE should be considered. Complications of prosthetic valve endocarditis such as abscess are readily assessed by TEE (Fig. 8.38). A pannus or thrombus may result in reduced or absent leaflet motion and prosthetic valve stenosis. Depending on the thrombus burden and the clinical status of a given patient, TTE and TEE may be used to guide and follow the response to intravenous thrombolytic therapy. Although the severity and cause of prosthetic valve regurgitation may not be easily

Figure 8.37 Continuous wave Doppler of an obstructed mechanical mitral valve prosthesis. Peak velocity 2.5 m/second; time velocity integral, 80 cm; mean gradient, 18 mm Hg; heart rate, 93 beats per minute. Arrow indicates mitral closing click.

Figure 8.38 Transesophageal echocardiography of prosthetic aortic valve vegetation (arrows) and abscess/pseudoaneurysm formation (Ab). Pseudoaneurysm demonstrates systolic expansion and occurs in endocarditis when an abscess ruptures and allows communication with the systemic circulation. LA, left atrium; LV, left ventricle.

determined by TTE because of acoustic shadowing, TEE is extremely useful in evaluating the degree of regurgitation and in identifying the site of origin and direction of perivalvular leaks. Unlike prosthetic mitral valves, adequate visualization and Doppler interrogation of prosthetic aortic valves can be challenging by TEE. Therefore, if doubt remains, one should consider biplane fluoroscopy to assess the mobility of aortic valve discs. Normal Doppler values for prosthetic valves in the aortic, mitral, tricuspid, and pulmonary positions are shown in [Table 8.5](#).

PERICARDIAL DISEASE

The detection of pericardial effusion generated much of the early interest in ultrasound as a useful cardiac diagnostic tool.⁷⁶ Today, echocardiography is routinely used to diagnose and manage pericardial disease. Pericardial effusion,

Figure 8.39 Long-axis view of large postoperative loculated posterior effusion. DAo, descending aorta; LV, left ventricle; RV, right ventricle.

Figure 8.40 Short-axis view of the left ventricle demonstrating large posterior postoperative loculated collection of pericardial fluid (EFF). LV, left ventricle.

tamponade, and, to a lesser extent, pericardial constriction, can be readily and reliably assessed with echocardiography.

On 2D echocardiography, findings of pericardial effusion include an echo-free space adjacent to the heart as well as absence of pericardial motion ([Fig. 8.39](#)). Effusions are termed small, moderate, and large ([Fig. 8.40](#)) based on the visually estimated volume of fluid, its location (posterior only or circumferential), and the size of the heart relative to the size of the fluid space. The subcostal view is particularly useful for identifying pericardial effusions ([Fig. 8.41](#)). Large effusions may occasionally result in “swinging” of the heart within the pericardial space, a phenomenon that correlates with the electrical alternans noted on the ECG.⁷⁷ Loculated pericardial effusions can be identified in patients after cardiac surgery and in patients who sustain chest trauma. In these circumstances, the effusion is localized to a single area of the pericardial space. It is important to note that rapid development of a relatively small volume of fluid in a critical location may quickly result in hemodynamic compromise. Relatively small, localized hematoma in patients after cardiac surgery, percutaneous intervention, electrophysiology study, or trauma can create a compressive effect that compromises cardiac hemodynamics ([Fig. 8.42](#)).

Figure 8.41 Subcostal view of inferoposterior pericardial effusion. The right ventricle is slit-like. LV, left ventricle.

Figure 8.42 Subcostal view of intrapericardial hematoma (H). LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

Pericardial tamponade occurs when, in the presence of fluid accumulating in the pericardial space, the pressure in the pericardium exceeds the pressure in the cardiac chambers, resulting in impaired filling and reduction of stroke volume and cardiac output, eventuating tachycardia, hypotension, and jugular venous distention.⁷⁸ The physiologic consequences depend on the amount of fluid, the rate of accumulation, the distensibility of the pericardium, and the compliance of cardiac chambers.⁷⁹ Tamponade may result from accumulation of fluid, pus, blood, clots, or gas within the pericardium. There are several echocardiographic features of pericardial tamponade. Pericardial effusion, usually at least moderate in volume, must be present (unless acute as described earlier). As the pressure within the pericardium increases, cardiac chamber collapse will ensue.⁸⁰ Impairment of filling is sequential: The atria will collapse before the higher pressure ventricles.⁸¹ The compressive effect of fluid is seen when the pressure is lowest in the chamber; RA collapse begins in late ventricular diastole (before or at the P wave) and should persist through at least one third of ventricular systole (Fig. 8.43). RA collapse occurs early in the course of tamponade but is a less specific marker than collapse of the right ventricle because the thin-walled right atrium can invert in the absence of tamponade when there is intravascular volume depletion. RV collapse occurs in early diastole.⁸² This finding will manifest later in the continuum but is more specific for significant hemodynamic compromise.⁸³ RV collapse is best appreciated when the ultrasound beam is perpendicular to the RV outflow tract from subcostal or parasternal views (Fig. 8.44). Timing of the onset and duration of RV collapse can be appreciated with M-mode (Fig. 8.45). Right-sided chamber collapse may be absent when tamponade occurs in the setting of severely elevated right-sided filling pressures (pulmonary hypertension).⁸⁴ When the effusion is loculated behind the left ventricle in the setting of reduced LV volumes, as might be seen in postoperative patients, diastolic collapse of the LV may

be the only indicator of hemodynamic compromise. A dilated inferior vena cava (IVC) that does not change dimension with respiration is also consistent with elevated intrapericardial pressures (Fig. 8.46), although this finding is nonspecific in intubated patients owing to positive intrathoracic pressures.

Reciprocal respiratory changes in RV and LV volumes become evident in tamponade, and increased right heart filling occurs at the expense of left heart filling in a process mediated by the pericardium. RV volume increases with inspiration, shifting the septum toward the left ventricle in diastole and toward the right ventricle in systole. RV volume decreases with expiration, normalizing septal motion as LV filling increases (Figs. 8.47 to 8.49). These findings correspond to the clinical finding of pulsus paradoxus. Transvalvular Doppler flow velocities demonstrate respirophasic changes in tamponade as well.⁸⁵ Initial transmitral velocities are enhanced with expiration and diminished (>25%) with inspiration in tamponade; transtricuspid flow augments with inspiration and diminishes with expiration (Figs. 8.50 and 8.51). Correspondingly, the RV outflow TVI increases with inspiration while the LV outflow TVI decreases. These

are useful findings but can be difficult to demonstrate with precision in the acutely ill patient.

Echocardiography has been used to guide the percutaneous drainage of pericardial fluid.⁸⁶ Subcostal imaging is valuable in demonstrating the amount of inferior fluid in the typical location accessed by the subxiphoid needle approach, as well as determining the optimal site of puncture. Imaging from the cardiac apex in patients with large circumferential effusions can aid in determining needle position and guide advancement, although identifying the needle tip can occasionally be problematic. Once needle position is deemed appropriate and initial aspirate is obtained, an injection of a small amount of agitated saline confirms correct needle position within the pericardium⁸⁷ (Fig. 8.52).

Constrictive physiology is present when the visceral and parietal layers of the pericardium become adherent and fibrotic, resulting in marked impairment of LV filling. Chronic constrictive pericarditis is usually not associated with free pericardial fluid. The echocardiographic findings in constriction include a thickened pericardium (pericardial thickening may not be uniform); normal LV size with LA dilatation; abrupt termination of ventricular filling in

early diastole (best seen on M-mode); interventricular septal motion demonstrating a diastolic inward “bounce” in early diastole; and dilatation of the IVC. In addition, there is Doppler flow evidence of ventricular interaction with exaggerated respirophasic changes in transvalvular velocities, and dilated and plethoric IVC, like those seen in tamponade (Figs. 8.47 to 8.49, 8.53). Tissue Doppler imaging (TDI) evaluation of diastolic filling is useful in distinguishing

Figure 8.53 Ventricular interdependence in constrictive pericarditis. LV, left ventricle; RV, right ventricle. (Courtesy of Miguel Quinones, Methodist DeBakey Heart Center, Houston, TX.)

between pericardial constriction and restrictive cardiomyopathy, as there is commonly substantial overlap of spectral Doppler findings in these entities because both share features of limited or restrictive ventricular diastolic filling. Data suggest that the mitral annulus early diastolic velocity (Ea) by TDI is usually higher in patients with constrictive pericarditis (Fig. 8.54) than in those with primary restrictive cardiomyopathy, as the rate of LV relaxation is impaired in patients with restrictive cardiomyopathy.^{88,89}

AORTIC DISEASE

Although TEE is the preferred method for evaluating the aorta, transthoracic imaging can visualize the proximal ascending aorta and can occasionally identify an intimal flap from aortic dissection (Fig. 8.55), either from the parasternal views or from the suprasternal notch. In addition, TTE can evaluate the integrity of the aortic valve and quantify the degree of AR; can recognize any LV wall motion abnormalities (but in this setting TTE cannot distinguish between primary ischemia and ischemia secondary to coronary extension of the dissecting flap); and can identify any associated pericardial effusion. It is important to note that, as seen in aortic aneurysms, patients with dissection very often have significant aortic dilation; thus, lack of aortic dilation may argue against dissection. However, overall, the sensitivity of

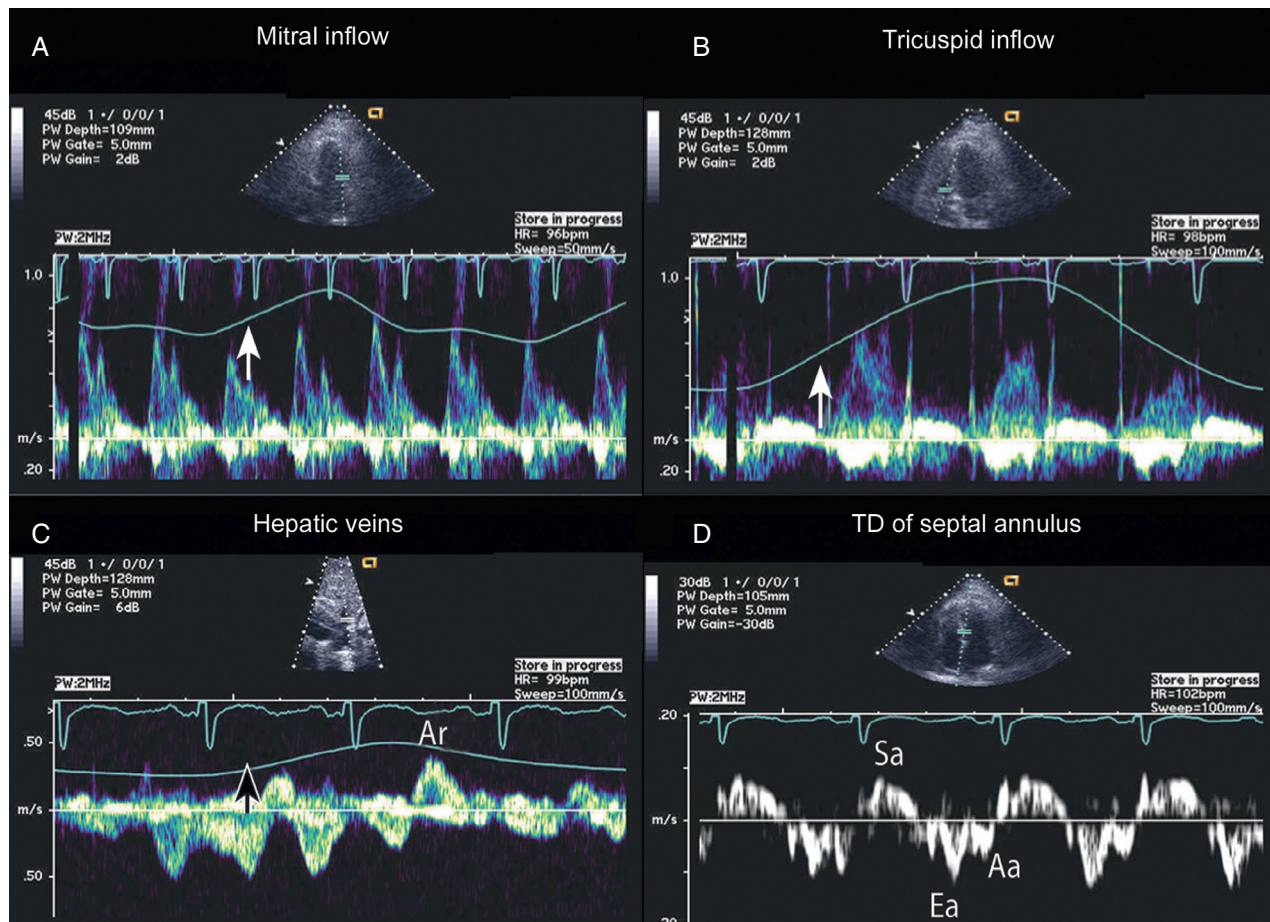

Figure 8.54 Doppler patterns in constrictive pericarditis. **A**, Respiratory variation (arrow: inspiration) in mitral inflow. **B**, Tricuspid inflow variability (arrow: inspiration). **C**, Increase in diastolic hepatic flow reversal after expiration (Ar). **D**, Tissue Doppler of septal annulus; Ea velocity 10 cm/sec, consistent with pericardial constriction. Figure 8.56 Transesophageal echocardiography image of proximal intimal dissection flap (white arrow). Red arrow indicates aortic valve. LA, left atrium; LV, left ventricle.

TTE for the diagnosis of dissection in the aortic arch and descending aorta is low, and TEE (or other modalities such as computed tomography [CT] scanning) is often indicated. The close proximity of the esophagus to the aorta makes TEE the superior modality for the evaluation of aortic dissection, with both sensitivity and specificity of 98%.⁹⁰⁻⁹⁴ The ascending aorta, aortic arch, and descending thoracic aorta can be visualized with excellent resolution. TEE can be performed rapidly and safely at the bedside. Particular attention must be given to ensuring adequate sedation to avoid hypertension, tachycardia, or gagging in patients with suspected dissection. Common features of dissection on TEE imaging include:

- An intimal flap that moves toward the false lumen in systole (Fig. 8.56)
- Color Doppler flow in both the true and the false lumens
- Color flow identification of entry/exit sites
- Stasis or thrombosis within the false lumen
- Intramural hematoma (IMH)

IMH, originally described as bleeding into the outer layers of the aortic media due to rupture of the vasa vasorum

Figure 8.57 Transesophageal echocardiography of intramural hematoma (H). Ao, aorta.

Figure 8.58 Transesophageal echocardiography of grade 5 atheromatous debris (arrows). This was an incidental finding.

without a primary tear, appears as crescentic thickening of the aortic wall greater than 0.7 cm in the absence of a frank dissection flap (Fig. 8.57).⁹⁵ Considered a variant of overt aortic dissection, IMH is an important diagnosis to make, as data suggest IMH is a lethal condition when it involves the ascending aorta, and 16% of patients with IMH have evidence of evolution to classic aortic dissection on serial imaging.^{96,97}

TEE is also very useful for identifying aortic atherosclerotic plaque (Fig. 8.58) in patients with systemic embolism (particularly stroke), as described in more detail subsequently.

CARDIAC TRAUMA

Blunt cardiac trauma occurs in the presence of evidence of external thoracic impact, such as chest wall contusions, hematomas, and fractured ribs/sternum, which is distinguished from great vessel trauma that can occur in rapid deceleration injuries. Virtually any cardiac structure can be impacted by blunt thoracic trauma and can result in significant risk of morbidity and death. Cardiac contusion is a common result of blunt thoracic trauma and is

echocardiographically characterized by mainly RV—but also LV—global or regional dysfunction. Valve disruption with severe valvular regurgitation can occur; the most common valves to be disrupted are the tricuspid and mitral valves, respectively.⁹⁸ For cases of cardiac contusion, troponin levels can be helpful as negative serial troponins can argue against significant cardiac contusions.⁹⁹ Penetrating cardiac trauma is most often the result of bullet or knife penetration to the thorax but can occur from a variety of accidents. Echocardiographically, the most common manifestations of penetrating cardiac injuries are pericardial effusion/tamponade, although projectiles can at times be seen on echocardiography of the cardiac chambers. Although echocardiography has a vital role in the diagnosis and management of cardiac trauma, other imaging modalities such as radiography, CT, and magnetic resonance imaging (MRI) play important roles.

TEE is quite useful in the evaluation of the aorta following blunt injury, usually a result of high-speed deceleration accidents.^{100,101} Traumatic disruption of the aorta usually involves the region of the aortic isthmus, the aortic segment between the left subclavian and the first intercostal arteries. Blunt injuries that can be identified by TEE include the more minor localized hematoma, limited intimal flaps, and mural thrombus (injuries not requiring surgical intervention), and the significant subadventitial rupture or complete transection (injuries that require urgent surgical intervention). Subadventitial disruption commonly demonstrates a localized “thick medial flap” on TEE in association with significant change in the contour of the isthmus, or complete rupture with pseudoaneurysm formation can be seen.

INTRACARDIAC SHUNTS

Intracardiac shunts are either congenital (for example, ASD, VSD, PFO) or can be acquired, often in the setting of acute myocardial infarction (infarct-related VSD) or at times in the presence of penetrating cardiac trauma. From the critical care perspective, the important manifestations

of cardiac shunts are heart failure and pulmonary hypertension from longstanding congenital lesions (for example, large ASD), stroke from right-to-left shunting in the presence of deep venous thrombosis, and persistent hypoxia resistant to oxygen therapy in the setting of right-to-left shunting. Although the discussion of congenital cardiac shunts is beyond the scope of this chapter,¹⁰² any patient with history of cardiac surgery/intervention as a child or young adult should undergo echocardiography in the critical care setting to assess for congenital lesions, as should cyanotic or hypoxic individuals without such a history who are in critical care. Because paradoxical embolism—from the deep venous system into the vena cava, then right atrium and across into the left side of the heart—can cause embolic stroke, patients with stroke in critical care should, in the right clinical setting, be assessed for intracardiac shunt.¹⁰³ This is performed using color Doppler imaging of the interatrial septum, and if negative, followed by agitated saline contrast injection into the systemic veins, as described earlier. For patients in critical care with persistent hypoxia without obvious cause, right-to-left intracardiac shunting of deoxygenated blood can at times be the cause. In such scenarios, color Doppler interrogation including saline contrast injection under echocardiographic guidance as described previously can be of great utility (see Fig. 8.3).

HEMODYNAMIC ASSESSMENT

It is possible to calculate blood flow at several levels in the heart and aorta using Doppler echocardiography.¹⁰⁴ Such measurements of flow can be very useful in the ICU setting to derive LV stroke volume, cardiac output, regurgitant volumes of MR and AR, flow across an ASD or VSD, valve areas (by continuity principle), and the response to therapeutic measures such as intravenous administration of inotropic drugs or the effect of an intra-aortic balloon pump on systemic output. Stroke volume in mL (or cm³) is calculated as the product of the cross-sectional area (cm²) of the LVOT and the TVI (cm) by PW Doppler (Fig. 8.59) at this

Figure 8.59 Method for stroke volume (SV) calculation using aortic annulus and aortic time velocity integral (TVI). $SV = CSA \times TVI$. Ao, aorta; CSA, cross-sectional area; LA, left atrium; PLAX, parasternal long-axis view.

Figure 8.60 Method for calculation of right ventricular systolic pressure (see text). PASP, pulmonary artery systolic pressure; RA, right atrial; TR, tricuspid regurgitant velocity.

site.^{105,106} Cardiac output can then be calculated as the product of stroke volume and heart rate. A number of studies have shown good accuracy of Doppler echocardiography when compared against measurements derived by thermodilution, including data obtained from patients in the ICU. Doppler-derived stroke volume can provide important clues in situations of reduced output (be it due to volume depletion or LV systolic dysfunction) as well as cases of high-output states such as sepsis and liver failure.

Peak PA systolic pressure is calculated from the peak Doppler velocity (v) of TR by CW (Fig. 8.60). Using the modified Bernoulli equation, the peak systolic gradient (ΔP) in mm Hg between the right ventricle and the right atrium is given by $4v^2$ (where v is in m/second). An estimate of RA pressure is then added to ΔP to estimate peak RV systolic pressure, and in the absence of pulmonary stenosis, peak PA systolic pressure.¹⁰⁷ RA pressure can be estimated from the change in IVC diameter with spontaneous breathing, as recorded from subcostal views. Normal variation or collapse of the IVC with breathing (>50%) implies normal RA pressure (0–5 mm Hg). Partial collapse (<50%) is generally estimated at 5 to 10 mm Hg, whereas no (or only minimal) change in IVC diameter implies an RA pressure of 15 mm Hg or more. When available, RA pressure can be obtained directly from a central venous pressure tracing, which is more accurate. In addition, hepatic venous flow may be used, particularly in patients on mechanical ventilation. Similar to pulmonary venous flow, a high RA pressure is associated with decreased RA filling from the hepatic veins during systole and increased filling during diastole (small S wave, large D wave). This measurement has been shown to have a good correlation with invasively measured RA pressure.¹⁰⁸

STROKE AND OTHER SYSTEMIC EMBOLI

From 17% to 25% of all strokes are cardioembolic in origin.¹⁰⁹ Echocardiography, particularly TEE, is commonly used to search for potential cardiac sources of arterial emboli, the most common of which are atrial fibrillation (AF) with LA appendage thrombus, primary or metastatic

Figure 8.61 Transesophageal echocardiography of large mass (M) invading both atria with associated mobile thrombus in a patient who presented with bilateral upper extremity emboli and was found to have metastatic lung cancer. Ao, aorta; LA, left atrium; RV, right ventricle.

Box 8.3 Echocardiographic Evaluation of Cardiac Source of Embolus

- Intracardiac thrombus
 - Ventricular (apex)
 - Atrial (body of left atrium, left atrial appendage)
 - Prosthetic material (valves, monitoring lines, pacer wires)
 - Spontaneous contrast
- Valvular vegetations
- Patent foramen ovale/atrial septal defect
- Atrial septal aneurysm

 - Primary (myxoma, fibroelastoma)
 - Metastatic (lung, breast)
- Mitral valve prolapse
- Mitral annular calcification
- Aortic annular calcium
- Atheromatous debris of the aorta

LA tumor (see Fig. 8.61), atheromatous disease of the aorta (see Fig. 8.58), LV apical thrombus (see Fig. 8.13), and PFO with/without atrial septal aneurysm (ASA).^{110,111} Although color Doppler may occasionally demonstrate a right-to-left shunt at the atrial level, injection of agitated saline in this setting is particularly useful in determining right-to-left bubble crossover (see Fig. 8.3). AF predisposes to thrombus formation in the body of the left atrium and in the LA appendage. Although transthoracic imaging can identify abnormalities that predispose to AF, such as mitral stenosis, TEE is necessary for a thorough assessment of the body of the left atrium and of the LA appendage, which is the most common site of thrombus formation in AF.^{112,113} A significant association exists between aortic atheroma and stroke.¹¹⁴ TEE reliably identifies aortic debris and can determine location, morphologic characteristics, and mobility of identified lesions (see Fig. 8.58).^{113–115} The most common disorders associated with stroke identified by echocardiography are listed in Box 8.3.

SUMMARY

Echocardiography with Doppler is a vital tool in the assessment of patients in critical care. Ventricular function and complications of myocardial infarction can be determined; the presence and significance of pericardial effusion can be assessed; hemodynamically significant valve disease can be quantified; presence and extent of infective endocarditis can be assessed; fundamental intracardiac hemodynamics can be calculated; cardiac complications of trauma can be noted; potential cardiac causes of stroke can be determined; and the assessment of aortic disease can reliably be accomplished. When TTE does not produce diagnostic images or when pertinent clinical questions remain unanswered, TEE can readily provide additional morphologic and hemodynamic information that can impact patient management and outcome in the critical care setting.

KEY POINTS

- Echocardiography is an invaluable noninvasive tool for the detection of cardiovascular abnormalities in the critical care setting.
- TEE should be used to provide more detailed or more comprehensive information when transthoracic images are inadequate. TEE may be considered for the evaluation of the aorta, for the assessment of native and prosthetic valves, and for the evaluation of intracardiac shunting.
- Commercially available contrast agents for LVO can now salvage many otherwise uninterpretable transthoracic studies.
- Echocardiography offers a number of reasonably accurate methods to assess global LV systolic properties, including EF using 2D imaging and tissue Doppler imaging. Stroke volume and cardiac output can also be reliably determined in most patients by echo-Doppler.
- Echocardiography now offers numerous methods to determine LV filling pressures with reasonable accuracy. A reliable assessment of LV dimensions and EF, when combined with knowledge of filling pressures, can be used to guide and assess the response to therapeutic measures.
- PA systolic and diastolic pressures can be calculated with confidence in many patients in the critical care setting.
- Mechanical complications of myocardial infarction, including acute MR, VSD, pseudoaneurysm formation, and LV thrombus, are readily evaluated with echocardiography.
- Although the echocardiographic assessment of the right ventricle is still challenging because of its complex shape, it is possible to integrate information from multiple views to reach reasonably accurate

KEY POINTS (Continued)

- conclusions regarding RV size and function, particularly in the setting of RV pressure or volume overload.
- Echocardiography is particularly well suited to the evaluation of cardiac valve anatomy, morphologic features, and motion. The integration of 2D anatomy with spectral and color Doppler methods of quantifying obstructive and regurgitant lesions provides a comprehensive assessment of valvular disease. TEE may be needed to evaluate prosthetic valves and approaches to surgical repair.
- Pericardial effusion can be localized and quantified, and its hemodynamic impact can be assessed, with thoughtful application of imaging and Doppler techniques. In the setting of trauma and the cardiac surgical postoperative state, opportunistic loculated effusions must be identified.

General Principles of Mechanical Ventilation

Brian M. Fuller | Ismail Cinel | R. Phillip Dellinger

CHAPTER OUTLINE

HISTORY

MECHANICAL VENTILATION

Basic Concepts

The Ventilatory Circuit

Alarms and Safety

Automatic Tube Compensation

INDICATIONS FOR MECHANICAL VENTILATION

MECHANICAL BREATH GENERATION

VENTILATOR MODES

Continuous Mandatory Ventilation

Assist Control Ventilation

Synchronized Intermittent Mandatory Ventilation

Stand-Alone Pressure Support Ventilation

Dual Control Modes

OTHER MODES OF MECHANICAL VENTILATION

Airway Pressure Release Ventilation

High-Frequency Oscillatory Ventilation

Effort-Adapted Modes of Mechanical Ventilation

POSITIVE END-EXPIRATORY PRESSURE

MONITORING THE VENTILATED PATIENT

Hemodynamics

Pulse Oximetry

End-Tidal Capnography

Ventilator Waveforms

MAINTAINING SUPPORT OF THE VENTILATED PATIENT

Sedation and Analgesia

Positioning

Secretion Clearance

WEANING FROM MECHANICAL VENTILATION

COMPLICATIONS OF MECHANICAL VENTILATION

Hemodynamics

Ventilator-Induced Lung Injury

Ventilator-Associated Pneumonia

Gastrointestinal Bleeding

Venous Thromboembolism

NONINVASIVE POSITIVE-PRESSURE VENTILATION

Management of the mechanically ventilated patient is a cornerstone of critical care training and practice. The institution of mechanical ventilation can be a lifesaving measure. However, the mechanical ventilator also has potential for great harm and, in and of itself, does not reverse underlying disease. Limiting iatrogenic injury from ventilator-induced lung injury (VILI) should take high priority, along with acceptable levels of oxygenation and ventilation. The clinician should be aware of basic and advanced principles involving mechanical ventilation, allowing flexibility when applying evidence-based practices to the individual patient. Knowledge of guidelines and large clinical trials is vitally important, and the consideration of patient trajectory, individual physiology, timing of therapy, and severity of illness will make tailoring the ventilator prescription most effective.¹

HISTORY

Hippocrates (460-370 BC) likely gave the first description of endotracheal intubation in his "Treatise on Air," in which he states that "One should introduce a cannula into the trachea along the jawbone so that air can be drawn into the lungs."² In 1530, Paracelsus (1493-1541) used a fire bellows connected to a tube inserted into a patient's mouth as a ventilator device.³ The first known mechanical device designed specifically to provide ventilation for the patient was the foot pump developed by Fell and O'Dwyer in the 1880s.⁴

The first generation of mechanical ventilators focused primarily on the intermittent delivery of a bulk volume of gas to the patient with limited monitoring.⁵

Negative-pressure ventilators were invented and applied a negative pressure around the body or chest cavity. Two classic devices that provided negative-pressure ventilation were the iron lung and the chest cuirass or chest shell.⁶ Iron lungs were widely used during the poliomyelitis epidemics of the 1930s and 1940s. These devices encased the patient from the neck down and applied negative pressure around the patient to expand the lungs. The chest cuirass was intended to alleviate the problems of patient access and “tank shock” that occurred secondary to venous pooling during the application of negative pressure associated with iron lungs.⁷ Although the chest cuirass improved patient access and decreased the potential for tank shock, ventilation with this device was limited by the difficulties in maintaining an airtight seal between the shell and the patient’s chest wall.

After the polio epidemic of the 1960s, the era of respiratory intensive care emerged, as positive-pressure ventilation via an artificial airway became commonplace.⁶ Controlled mechanical ventilation eventually led to assisted modes of support, and positive end-expiratory pressure (PEEP) was introduced in the late 1960s. The improvements in mechanical ventilators came about as understanding was gained in manipulating variables of flow and pressure for patient benefit. Further technical evolution of ventilators included advances such as intermittent mandatory ventilation, and synchronous intermittent mandatory ventilation. Modern ventilators now boast microprocessors that serve both in the operating mechanism of the device and in the monitoring systems, enabling automatic adjustment of most aspects of the mechanical breath being delivered.

MECHANICAL VENTILATION

BASIC CONCEPTS

For a breath to be generated, a pressure gradient must exist. During normal spontaneous breathing, the diaphragm and other respiratory muscles create gas flow by lowering pleural, alveolar, and airway pressures relative to atmospheric pressure. Alveolar pressure is normally atmospheric at end-inspiration and end-expiration. Diaphragmatic and intercostal muscle activation during normal inspiration expands the chest and decreases intrapleural pressure from -5 cm H₂O to -8 cm H₂O. Alveolar pressure fluctuates from $+1$ cm H₂O during exhalation to -1 cm H₂O during inspiration.

A ventilation/perfusion (\dot{V}/\dot{Q}) mismatch occurs when areas of the lung are perfused but either poorly ventilated (low \dot{V}/\dot{Q}) or not ventilated at all (shunt). The latter is an intrapulmonary (IP) (capillary) shunt. Shunt may also be intracardiac (anatomic). Venous admixture, as a measure of less than fully oxygenated blood after passing through the lung, includes both low \dot{V}/\dot{Q} areas of lung and IP shunt. Normal venous admixture is about 2% to 5%. Mechanical ventilation may increase the venous admixture to approximately 10% in the normal individual. Mechanical ventilation usually decreases venous admixture in alveolar lung disease, such as acute lung injury (ALI), improving the distribution of ventilation especially in previously underventilated lung areas. Pressures greater than alveolar opening

and closing pressures expand the collapsed alveolus and prevent its collapse, respectively. However, if positive-pressure ventilation produces overdistention, redistribution of pulmonary blood flow to unventilated regions may occur, resulting in hypoxemia. *Dead space* refers to areas of the lung with a higher \dot{V}/\dot{Q} ratio. *Anatomic dead space* is the volume of the conducting airways of the lungs, about 150 mL. *Alveolar dead space* refers to alveoli that are overventilated relative to perfusion; it is increased by any condition that reduces pulmonary blood flow, such as pulmonary embolism (PE) or with overdistention of the lung. *Mechanical dead space* refers to the rebreathed volume of the ventilator circuit; this volume behaves like an extension of the anatomic dead space. Mechanical ventilation can also increase dead space if it leads to overdistention.

An increased dead space fraction requires a greater minute ventilation to maintain alveolar ventilation and P_{aCO_2} (partial pressure of carbon dioxide in arterial blood). Hyperventilation lowers P_{aCO_2} . Hypoventilation raises P_{aCO_2} ; a modest elevation (50–70 mm Hg) reduces pH and is usually not by itself injurious in the mechanically ventilated patient. It has become increasingly recognized that hypercapnia during mechanical ventilation is well tolerated and may not be harmful. An exception occurs in the presence of increased intracranial pressure (ICP).

Although modern ventilators have evolved into complex machines, the basic premise remains: a ventilator is designed to replace or augment a patient’s muscles in performing the work of breathing.⁸ Ventilators use input power (electricity or compressed gas) to ventilate the lungs. To generate a breath (whether it be spontaneous or positive pressure), a pressure gradient must be generated from the airway opening to the alveoli. The volumes delivered and pressures generated largely depend on the mechanical properties of the respiratory system: the lungs and chest wall as well as the abdomen.⁸ Each of these components has mechanical properties that determine the overall behavior of the respiratory system. Although the respiratory system can be quite complex, the main *variables* of interest are pressure, flow, and volume. The ventilator must generate a *pressure* to cause *flow* through an open circuit and therefore increase lung *volume*.⁹ The pressure required to do this reflects a combination of the pressures to inflate the lung and chest wall. This can be illustrated by the equation of motion:^{9,10}

$$\begin{aligned} \text{Muscle pressure} + \text{Ventilator pressure} \\ = (\text{Elastance} \times \text{Volume}) + (\text{Resistance} \times \text{Flow}) \end{aligned}$$

Compliance describes the ease or difficulty of the respiratory system to expand in response to a delivered pressure and volume. Simplistically, compliance is defined by the change in volume (ΔV) divided by the change in pressure (ΔP), and the compliance of the respiratory system (C_{RS}) is $\Delta V/\Delta P_{\text{alveolar}}$. *Elastance* is the inverse of compliance, or the ratio of pressure change to volume change, and describes the tendency to recoil. *Resistance* describes the impedance to airflow through the respiratory system, or the ratio of pressure change to flow change. The *elastic load* is the pressure required to overcome the elastance of the respiratory system, and the *resistive load* is the pressure required to overcome flow resistance of the ventilator circuit, endotracheal tube, and airways.⁸

The equation of motion illustrates several basic principles. To drive gas into the patient, a ventilator can directly control either the pressure or the flow and volume applied at the airway. Despite its complexity a ventilator is simply a machine controlling one of these two variables (*control variables*). For example, in pressure control and pressure support ventilation (PSV), pressure is the control variable and is held constant, although flow and lung inflation will vary based on the patient's respiratory mechanics and inspiratory time (I time) (the latter set directly in pressure control and patient influence with pressure support). In volume ventilation, flow is the control variable and pressure and lung inflation vary with the patient's respiratory mechanics. Flow and volume are intimately linked: volume (L) = flow (L/second) × I time (second).

THE VENTILATOR CIRCUIT

The ventilator circuit consists of plastic tubing connecting the artificial airway or mask with the mechanical ventilator. Within the circuit may reside humidifiers, devices for the delivery of aerosolized medications, filters, suction catheters for secretion clearance, and heated wires.¹¹ The length and compliance (2-3 cm³/cm H₂O) of the ventilator circuit are responsible for a volume of gas contained within the circuit, termed the *compressible volume*. This is partly responsible for the discrepancy between the set tidal volume delivered and the expiratory volume measured and displayed by the ventilator. The ventilator circuit also adds resistance to the system, but is minimal when compared to either the patient's inherent mechanics or the endotracheal tube. Although frequently colonized with bacterial pathogens, the routine change of the ventilator circuit for infection prevention (e.g., ventilator-associated pneumonia) is not recommended.

In the body, inspired gases are conditioned in the airway just before the carina so that they are fully saturated with water at body temperature by the time they reach the alveoli (37° C, 100% relative humidity, 44 mg/L absolute humidity, 47 mm Hg water vapor pressure). This portion of the airway acts as a heat and moisture exchanger (HME). Under normal conditions, about 250 mL of water is lost from the lungs each day to humidify the inspired gases.

Gases delivered from mechanical ventilators are typically dry, and the upper airways of patients being ventilated are functionally bypassed by artificial airways, necessitating the use of an external humidifying apparatus in the breathing circuit. Because the upper airway is bypassed during mechanical ventilation, the inspired gas temperature should be kept close to the body temperature. Inspired gases that bypass the upper respiratory tract through endotracheal tubes or tracheostomy tubes should be heated to at least 32° to 34° C at 95% to 100% relative humidity. The temperature probe for the heated humidifier should be placed inside the inspiratory limb of the ventilator circuit as close to the patient as possible. Moisture loss and subsequent dehydration of the respiratory tract result in epithelial damage.

An HME, which is placed between the artificial airway and the ventilator circuit, may be used to replace the traditional heated humidifier. During exhalation, moisture and heat from the patient are absorbed into the honeycomb structure of the exchanger and are transferred back to the patient during the next inhalation. Ventilator circuits with

bacterial-viral filtering HMEs cost less to maintain and are less likely to colonize bacteria than those with heated humidifiers.^{12,13} Contraindications for use of an HME are thick or large amounts of secretions, minute volume exceeding 10 L/minute, body temperature less than 32° C, and need for aerosolized medications.¹⁴

ALARMS AND SAFETY

Current ventilators are equipped with monitors that constantly or periodically assess the ventilator's operation and the patient's status (Fig. 9.1). These monitors are usually associated with alarms that visually or audibly notify the operator of any variation from the preset norm. Ventilator alarms can warn of potentially life-threatening events, must have an appropriate level of sensitivity and specificity, and must be evaluated clinically and in a clinical context.¹⁵ There are some alarms related to *power input* (e.g., low battery, loss of power, loss of air supply) and *control circuit* (e.g., nonfunctioning ventilator, incompatible settings), but most alarms are related to measured *output*, such as pressure, volume, and flow.⁸

High-pressure alarms are triggered by patient factors (such as decreased compliance and increased resistance of the respiratory system) or by ventilator circuit malfunction (obstruction or kinking of the endotracheal tube). Low-pressure alarms are generally secondary to a leak in the system (ventilator circuit, endotracheal tube or cuff) or patient (large pressure loss from a bronchopleural fistula). A high expired volume alarm could be seen with improved pulmonary mechanics during pressure-control ventilation. Low expired volume could be secondary to patient-ventilator disconnect or a leak in the system or patient. A high-frequency alarm is secondary to either autotriggering or hyperventilation, and a low-frequency alarm indicates bradypnea or apnea.^{8,15}

AUTOMATIC TUBE COMPENSATION

Traditionally, most clinicians apply some amount of pressure support during inspiration to compensate for the increased work of breathing related to artificial airway resistance. The amount of pressure support needed to counterbalance this resistance is highly variable, depending not only on the internal diameter of the endotracheal tube but also on flow, bend of the tube, and changing demands of the patient. This variability makes one level of pressure insufficient to meet these changing demands.¹⁶

Automatic tube compensation (ATC) compensates for endotracheal tube resistance via closed-loop control of calculated tracheal pressure. A ventilator with ATC compensates for the pressure drop across the endotracheal tube during inspiration by increasing the airway pressure and during expiration by decreasing airway pressure according to actual gas flow.¹⁷⁻¹⁹ This technique uses a continuous calculation of the flow-dependent drop in pressure across the endotracheal tube. ATC is similar to PSV, but the pressure applied by the ventilator varies as a function of endotracheal tube resistance and flow demand. Most of the interest in ATC revolves around eliminating the imposed work of breathing during inspiration. During expiration, however, ATC may also compensate for that flow resistance by lowering the pressure in the expiratory limb transiently from its

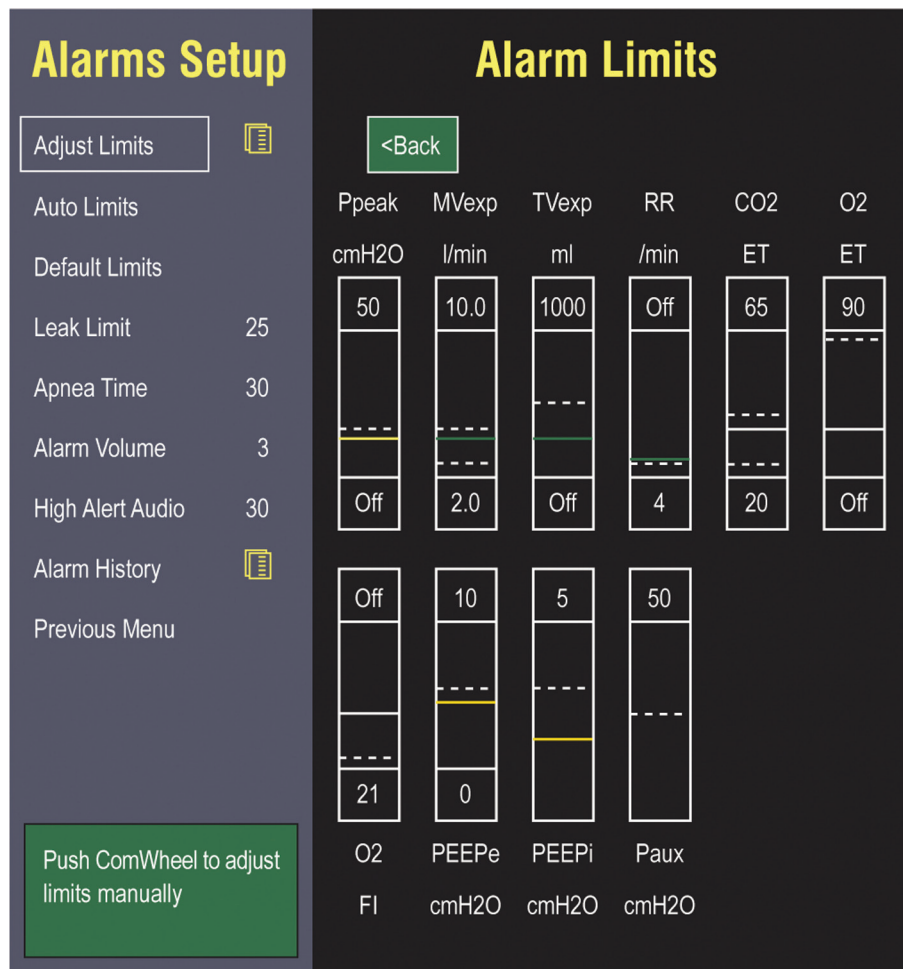

Figure 9.1 The alarm panel of a Draeger Evita 4 ventilator showing the alarms typically used on current ventilators. (Reproduced with permission from Draeger Medical, Inc., Lübeck, Germany.)

PEEP setting, helping reduce effective expiratory resistance and auto-PEEP.^{17,20} In addition to overcoming the work of breathing imposed by the artificial airway, ATC may improve patient-ventilator synchrony by varying the flow commensurate with demand and may reduce air trapping by compensating for imposed expiratory resistance. During weaning trials, this technique may allow a more reliable prediction of patient performance when the tube is removed.

INDICATIONS FOR MECHANICAL VENTILATION

Mechanical ventilation is instituted for a number of reasons (Table 9.1).²¹ Most commonly, these indications are a combination of a failure to adequately oxygenate, ventilate, or meet the metabolic demands of a physiologically stressed patient. Clinical indicators such as tachycardia, arrhythmias, hypertension, and tachypnea, use of accessory respiratory muscles, diaphoresis, and cyanosis are used to diagnose respiratory distress. Type I respiratory failure is hypoxemic respiratory failure, defined as a partial pressure of oxygen in arterial blood (P_{aO_2}) less than 60 mm Hg. Type II respiratory failure is hypercarbic respiratory failure, defined as P_{aCO_2} greater than 50 mm Hg, if elevated from patient

baseline and associated with acidosis.²² Blood pH is generally a better indicator than P_{aCO_2} for adjusting minute ventilation. Hypercapnia should not prompt aggressive intervention if pH remains acceptable and the patient remains alert. Hypercapnia is generally well tolerated, but this clearly depends on the underlying pathophysiology and comorbid conditions of the patient (e.g., right ventricular dysfunction). However, a sustained pH of 7.65 or greater or 7.10 or less is often considered sufficiently dangerous in itself to require control of minute ventilation by mechanical ventilation. Mechanical ventilation may also be instituted to maintain normal blood pH, decrease work of breathing, assist left ventricular function in the setting of acute decompensated heart failure, or for airway protection in the setting of toxic overdose, traumatic brain injury, or any other significant acute central nervous system illnesses. Box 9.1 suggests guidelines for setting basic operating parameters in a mechanical ventilator.

MECHANICAL BREATH GENERATION

The breath generated by a mechanical ventilator can be separated into four *phases*: triggering, inspiration, cycling, expiration.

Table 9.1 Potential Indications for Mechanical Ventilation

Physiologic Mechanism	Clinical Assessment	Normal Range	Value(s)/Finding(s) Supporting Need for Mechanical Ventilation
Hypoxemia	P(A – a)O ₂ gradient (mm Hg)	25–65	>350
	PaO ₂ /FIO ₂ ratio	425–475	<300
	SaO ₂	98%	<90% despite supplemental oxygen
Hypercarbia/inadequate alveolar ventilation	PaCO ₂	35–45 mm Hg	Acute increase from patient's baseline pH <7.20 Mental status decline
Oxygen delivery/oxygen consumption imbalance	Elevated lactate	≤2.2 mg/dL	≥4 mg/dL despite adequate resuscitation
	Decreased mixed venous oxygen saturation	70%	<70% despite adequate acute resuscitation
Increased work of breathing	Minute ventilation	5–10 L/min	>15–20 L/min
	Dead space	0.15–0.30	≥0.5 (acute)
Inspiratory muscle weakness	NIP	80–100 cm H ₂ O	<20–30
	VC	60–75 mL/kg	<15–20
Acute decompensated heart failure	Jugular venous distention		Clinical judgment combined with the listed factors
	Pulmonary edema		
	Decreased EF		
Inadequate lung expansion	Vt (mL/kg)	5–8	<4–5
	VC (mL/kg)	60–75	<10–15
	Respiratory rate (breaths/min)	12–20	≥35

A – a, alveolar-arterial; EF, ejection fraction; NIP, negative inspiratory pressure; VC, vital capacity; Vt, tidal volume.

Box 9.1 Guidelines for the Initiation of Mechanical Ventilation

1. Choose the ventilator mode with which you are most familiar. The primary goals of ventilatory support are adequate oxygenation/ventilation, reduced work of breathing, synchrony between the patient and ventilator, and avoidance of high end-inspiratory alveolar pressures.
2. The initial FIO₂ (fraction of inspired oxygen) value should be 1.0. The FIO₂ thereafter can be titrated downward to maintain the SpO₂ (oxyhemoglobin saturation) at 92% to 94%. In severe acute respiratory distress syndrome (ARDS), >88% SpO₂ may be acceptable to minimize complications of mechanical ventilation.
3. Initial tidal volume (Vt) should be 8–10 mL/kg. Patients with acute respiratory failure (ARF) from neuromuscular disease often require Vt of 10–12 mL/kg to satisfy air hunger. In patients with ARDS, it is recommended to use a Vt of 6 mL/kg and to keep inspiratory plateau pressure (IPP) 30 cm H₂O or less.
4. Choose a respiratory rate and minute ventilation appropriate for the particular clinical requirements. Target pH, not PaCO₂. Initial respiratory rate is typically 10–12 breaths/min.
5. Use positive end-expiratory pressure (PEEP) in diffuse lung injury to support oxygenation and reduce the FIO₂.
6. In patients with COPD, avoid choosing settings that limit expiratory time and cause or worsen auto-PEEP.
7. When poor oxygenation, inadequate ventilation, or excessively high peak inspiration pressures are thought to be related to patient intolerance of ventilator settings and are not corrected by ventilator adjustment, consider initiating or increasing sedation or analgesia.

Adapted from Fundamental Critical Care Support, Des Plaines, IL, 2007, Society of Critical Care Medicine.

Triggering represents the change from expiration to inspiration and occurs either because of a drop in circuit pressure or diversion of flow (when patient triggered), or because of elapsed time. Sensitivity refers to a preset threshold of pressure or flow. When this threshold is reached, a mechanical breath is delivered. This threshold can be adjusted, and is usually set at –1 to –2 cm H₂O. If sensitivity is set too low, the ventilator will be triggered by any process that causes the airway pressure to drop below the set threshold. Such processes include patient motion, external compression, gastric suctioning, and air leaks in the circuit. Conversely, if the threshold is set too high, the work of breathing increases, as the patient must make a significant effort to overcome the threshold limit for inspiratory flow to occur. In the setting of pressure triggering, airway pressure is reduced (by patient effort) in the proximal circuit, the expiratory valve closes, pressurization of the inspiratory limb of the circuit occurs, and the patient receives a breath. Flow sensing was developed as an alternative to pressure triggering to reduce the delay in response time between neural input from the patient and delivery of gas volume by the ventilator.^{23,24} In the setting of flow triggering, the patient's inspiratory effort induces a disruption of the constant flow in the ventilator inspiratory circuit. This change in flow signals the expiratory valve to close and for the ventilator to deliver the next breath. Flow triggering was initially demonstrated to decrease the work of breathing when compared to pressure triggering. However, with improvement in response time, monitoring, and feedback, pressure and flow triggering are similar in this regard.^{25,26} Figure 9.2 is a representation of patient effort and ventilator response time.

During *inspiration*, pressurized gas is channeled from the ventilator to the patient after the exhalation valve closes.

Figure 9.2 Pressure wave showing time relationship between patient inspiratory effort and ventilator response time (RT).

Figure 9.3 A plateau pressure measurement can be obtained in assist volume control mode by the performance of an inspiratory hold to better estimate the pressure in the lungs.

This phase can be controlled by how one sets flow or pressure in the ventilator proximal to the open inspiratory valve. For example, volume-assist control is flow controlled and pressure-assist control is pressure controlled. Choice of control variable is largely the discretion of the clinician, as either can be manipulated to achieve set goals. It should be noted, though, that in volume-targeted ventilation, excessive airway pressures can arise secondary to worsening pulmonary mechanics. In this situation, the pressure alarm will cause a pressure limit to cycle to expiration. At the end of inspiration in volume-targeted ventilation, an inspiratory hold maneuver can be performed (Fig. 9.3), which can distinguish the peak airway pressure from the plateau pressure (because flow is stopped, resistance is negligible). In pressure-targeted ventilation, minute ventilation is not guaranteed. It is a function of the compliance and resistance of the respiratory system. The clinician therefore should monitor these physiologic changes closely to avoid untoward changes in either airway pressure or Paco_2 levels.

Figure 9.4 Depicted left to right are square, decelerating, and sine inspiratory flow waveforms as options for delivery of volume ventilation. Note that the square waveform produces the shortest inspiratory time and that the decelerating waveform does not return to zero flow at end inspiration. LPM, liters per minute; \dot{V} , flow.

With pressure control and pressure support (PS) breaths, the pattern of inspiratory flow is a natural decelerating pattern as the pressure gradient for flow decreases as pressure rises in the patient's lungs. The pattern of inspiratory flow with a flow-controlled breath is naturally square but can be computer altered to be *decelerating* or *sinusoidal* (Fig. 9.4). A square inspiratory flow pattern results in a rapid rise to a preset level (set by the clinician) followed by constant flow until cycling occurs. Decelerating flow results in a rapid rise to a maximum level followed by a gradual decrease until cycling. Sinusoidal flow pattern most closely represents normal physiologic breathing. It results in flow that gradually increases and then decreases during inspiration. The choice of inspiratory flow pattern should be based on patient characteristics, and a few common clinical scenarios should be familiar to the clinician. Square flow over time results in a shorter inspiratory time (I time), and therefore longer expiratory time (E time). For this reason it may be preferred in patients with obstructive physiology (chronic obstructive pulmonary disease [COPD] or asthma).^{27,28} It is also usually tolerated better in patients with demand for high minute ventilation, such as severe metabolic acidosis or elevated ICP. In this situation, there is a potential for dyssynchrony to occur during the progression of the inspiratory phase if decelerating flow is chosen. The tradeoff is higher peak airway pressures with a square waveform, which may be ameliorated if it leads to a reduction in hyperinflation and iPEEP. Decelerating flow results in a longer I time and likely a better distribution of flow. With pulmonary pathophysiology involving heterogeneous distribution of injury (ALI as the prototype example), decelerating flow is likely the best choice, as the longer I time can lead to more homogeneous distribution of ventilation. The distribution of ventilation can be quite different when the flow pattern changes. A decelerating flow pattern yields the most even distribution under most abnormal airway conditions.²⁹ Studies have also demonstrated that a decelerating flow pattern improves the geographic distribution of lung vibration as a presumed surrogate of airflow.³⁰ The length of inspiration depends on several factors. In the pressure control mode of ventilation, the clinician directly controls the I time and I:E ratio. With pressure support the patient primarily controls I time. In flow-controlled (volume-targeted) ventilation, the I time is a function of set tidal volume (V_T) and flow rate ($V_T/\text{inspiratory flow rate}$) as well as flow wave characteristics (shape). The end-inspiratory alveolar pressure, as measured by an end-inspiratory hold, is the same for a given tidal volume regardless of the type of ventilator breath.

Cycling is the transition from inspiration to expiration (closing inspiratory valve and opening expiratory valve). It can occur due to a threshold of decrease in flow, elapsed time, or delivered volume. *Flow-cycled breaths* are PS breaths. Because flow rate decreases dramatically as patient inspiratory effort decreases and then ceases, the patient exerts control not only of initiation of breath but also of its termination. When a predetermined decrement in flow occurs, inspiration is terminated and the patient cycles to expiration. This is typically set at 25% of initial flow, but can be manipulated based on different clinical conditions. For example, if a large leak occurs (bronchopleural fistula or ventilator circuit leak) it may be wise to set the cycle at a higher percentage of initial flow to terminate inspiration at the appropriate time. Strength and duration of patient inspiratory effort influence tidal volume. For safety reasons, PS breaths can be cycled due to excessive pressures (e.g., coughing during inspiration) or elapsed time (e.g., secondary to a leak in the system which would prolong inspiration). In *time-cycled breaths* (pressure control), inspiration is terminated after a preset interval, regardless of whether preset pressure has been achieved or a desired tidal volume has been delivered. Pressure is maintained at a preset level throughout inspiration, yielding a square pressure waveform. Pressure-targeted ventilation is time cycled, and the time can be adjusted to yield a precise inspiration/expiration (I:E) ratio. In *volume-cycled breaths* (flow controlled), the clinician has selected the targeted tidal volume. Volume is delivered until that volume is reached. Airway pressure is directly dependent on the tidal volume and the mechanical characteristics of the patient's respiratory system. For safety reasons, volume-cycled breaths will be pressure cycled if airway pressures exceed the pressure alarm limit. In this situation, the delivered tidal volume will not reach the set volume target unless the pressure alarm limit is increased.

During expiration, flow from the ventilator is stopped, the exhalation valve opens, and gas is allowed out from the lungs. This release occurs passively. Inspiratory flow should cease prior to expiration. If this does not occur, the patient will develop auto-PEEP or intrinsic PEEP (iPEEP). This is

most commonly seen in patients with expiratory flow limitation (COPD or asthma) or higher I:E ratios (see later).

VENTILATOR MODES

A ventilator mode describes ventilation over time and a set of specific combinations of breath characteristics delivered to a patient, including types of breaths, phase variables, and mandatory versus spontaneous breaths.¹⁶ Clinician familiarity, unit, and institutional practice patterns determine to a large extent the mode that is employed. Also, data showing definitive improvement in clinically relevant outcomes when comparing one mode to another are lacking. Patient need and response to therapy should guide mode selection. [Table 9.2](#) summarizes the features of some of the modes of mechanical ventilation, and [Table 9.3](#) lists some of their advantages and disadvantages. [Figure 9.5](#) also shows some characteristic waveforms of various modes of mechanical ventilation.

CONTINUOUS MANDATORY VENTILATION

With continuous mandatory ventilation (CMV), the patient has no influence on mechanical ventilation, and all breaths are mandatory. Patient-ventilator interaction is solely from the ventilator to the patient; it is time triggered and limited and cycled by the ventilator. Current ventilators do not have a CMV setting; this mode is essentially what is achieved when a patient on assist control (AC) ventilation has no interaction with the ventilator secondary to heavy sedation or neuromuscular blockade.

ASSIST CONTROL VENTILATION

In AC ventilation, a mandatory number of breaths are set and delivered with a set pressure or flow (assisted or unassisted), and if the patient's respiratory rate is higher than this backup setting (rate) additional assisted breaths to the preset pressure or flow are delivered. The target variable can be pressure (PC/AC) or volume (VC/AC).

Table 9.2 Overview of Features of Selected Modes of Mechanical Ventilation

Ventilator Mode	Trigger	Control	Cycling	Inspiratory Flow
Continuous mandatory ventilation (CMV)	Time	Flow or pressure	Volume or time	Selected or decelerating
Volume control/assist control (VC/AC)	Patient or time	Flow	Volume	Square, decelerating, or sinusoidal
Pressure control/assist control (PC/AC)	Patient or time	Pressure	Time	Decelerating
Synchronized intermittent mandatory ventilation (SIMV)	Patient or time	Pressure for patient breaths Flow (VC) or pressure (PC) for ventilator breaths	Flow for spontaneous breaths Volume or time for ventilator breaths	Decelerating for spontaneous breath Square (VC), decelerating (VC or PC), sinusoidal for spontaneous breaths
Stand-alone pressure-support ventilation (PSV)	Patient	None	Flow	Decelerating

Table 9.3 Potential Advantages and Disadvantages of Selected Modes of Mechanical Ventilation

Mode	Advantage(s)	Disadvantage(s)
Controlled mechanical ventilation (CMV)	Rests muscles of respiration	Requires use of heavy sedation/neuromuscular blockade
Assist volume control (AVC)	Reduced work of breathing Guarantees delivery of set tidal volume (unless peak pressure limit alarm is exceeded)	Potential adverse hemodynamic effects May lead to inappropriate hyperventilation and excessive inspiration pressures
Assist pressure control (APC)	Allows limitation of peak inspiratory pressures	Same as for AVC Potential hyperventilation or hypoventilation with lung resistance/compliance changes
Synchronized intermittent mandatory ventilation (SIMV)	Less interference with normal cardiovascular function	Increased work of breathing compared with assist control Patient may find it difficult to adjust to two different types of ventilator breaths
Stand-alone pressure-support ventilation (PSV)	Patient comfort Improved patient-ventilator interaction Decreased work of breathing	Apnea alarm is only backup Variable patient tolerance

Figure 9.5 Characteristic pressure-flow waveforms with breathing spontaneously and various types of ventilation. **A**, Spontaneous breath. Such breaths are spontaneous, and inspiratory flow is achieved by the negative pressure generated by the respiratory muscles. Expiration occurs as these muscles relax. The combination of mandatory ventilator breaths (B or C) with spontaneous breaths (with or without pressure support) is called synchronized intermittent mandatory ventilation (SIMV). **B**, Assist volume control (AVC) ventilation. The flow is constant and pressure increases throughout inspiration. **C**, Assist pressure control (APC) ventilation or pressure-regulated volume control (PRVC). The pressure is constant and flow decreases throughout inspiration. In PRVC, the level of applied pressure may vary from one breath to the next. **D**, Pressure support ventilation. The pressure is constant and flow decreases throughout inspiration. When the flow reaches one fourth of its initial value, inspiration ends (flow-cycled). The flow and respiratory time are determined by patient effort and level of pressure support applied. The tidal volume varies from one breath to the next.

SYNCHRONIZED INTERMITTENT MANDATORY VENTILATION

With synchronized intermittent mandatory ventilation (SIMV), the ventilator delivers a mandatory number of breaths with a set pressure or flow (assisted or unassisted), similar to AC. However, spontaneous breaths are delivered upon patient triggering during a timing window created around the delivery of mandatory breaths. These spontaneous breaths can be totally driven by patient effort or pressure-enhanced as pressure-controlled/flow-cycled (PS) breaths.

The ventilator will attempt to synchronize the delivery of this mandatory breath with the spontaneous effort of the patient (if effort is present). If the patient does not trigger a breath, then the ventilator will deliver a regularly scheduled mandatory breath (time triggered).

STAND-ALONE PRESSURE SUPPORT VENTILATION

This mode of ventilation is patient triggered, pressure controlled, flow cycled, with a decelerating flow inspiratory

waveform. Cycling to expiration typically occurs when flow rate decreases to a set percentage of inspiratory flow (typically 25% of initial inspiratory flow). However, if there is a leak in the system, inspiratory flow may never decrease to the cycle threshold. In this situation, for safety purposes, flow can be time cycled as well. During inspiration, the ventilator will adjust flow to maintain the preset pressure, and tidal volume is dependent on patient effort, as well as the mechanics of the respiratory system. Pressurization rate to the goal pressure is determined by the rise time, which can be adjusted on many ventilators. If the rise time is set too low, increased work of breathing can occur; if set too high, preset pressure may be exceeded (overshoot), causing early cycling to expiration. PSV is effective at decreasing patient effort and work of breathing.³¹⁻³³ Data suggest that most clinicians view PSV as a weaning mode of mechanical ventilation, despite its being fully capable of appropriate full support in patients with respiratory failure intact respiratory drive.³⁴

DUAL CONTROL MODES

The preceding modes of mechanical ventilation are classically referred to as “conventional” ventilator modes, which is purely arbitrary. Dual control modes of ventilation manipulate pressure or volume on either a breath-to-breath basis or within the same breath. Breath-to-breath modes include volume support (VS) and pressure-regulated volume control (PRVC), also called “pressure control volume guarantee.” VS is PSV (pressure limited, flow cycled) that uses tidal volume as a feedback to adjust the pressure support level.¹⁶ PRVC is pressure control ventilation (pressure limited, time cycled), but uses tidal volume as a conditional variable to adjust pressure to achieve desired tidal volume.

OTHER MODES OF MECHANICAL VENTILATION

AIRWAY PRESSURE RELEASE VENTILATION

Airway pressure release ventilation (APRV) has been described in the literature since 1987.³⁵ It is a time-triggered, pressure-controlled, time-cycled mode of mechanical ventilation that exactly resembles AC/PC with very extended I:E ratios if the patient is not spontaneously breathing.^{36,37} It has been described as continuous positive airway pressure (CPAP) with an intermittent time-cycled release phase to a set lower pressure. Whereas conventional modes of mechanical ventilation elevate airway pressure up from a set baseline to accomplish tidal ventilation, APRV employs very high I:E ratios to maintain mean airway pressure, and brief deflations to accomplish ventilation. When APRV is used in acute respiratory distress syndrome (ARDS) (primary use) short T_{low} is used whereas this mode can be used in patients without ARDS with longer T_{low} and is often called “bilevel positive airway pressure” (BiPAP) in that circumstance (Fig. 9.6). The expiratory valve in APRV also facilitates spontaneous breathing throughout the ventilatory cycle, facilitating ventilation. Because this mode is primarily used with ARDS with long T_{high} and very short T_{low} , breathing occurs primarily during T_{high} . Pressure high (P_{high}) is the baseline airway pressure that occupies most of the ventilatory cycle. Pressure low (P_{low}) is the release pressure and is set at 0 cm H₂O. Time high (T_{high}) is the length of time for which P_{high} is maintained and T_{low} is the length of time for which P_{low} is maintained. This is primarily semantics, but the term *APRV* implies longer I:E ratios than BiPAP, and a P_{low} setting of 0 at all times.

Although outcome data are lacking compared to conventional ventilation using protective lung strategies, the

Figure 9.6 Pressure-time waveforms showing the use of airway pressure release ventilation (APRV). **A**, APRV with pressure-supported breaths. **B**, Bilevel positive airway pressure (BiPAP) with pressure-supported breaths.

reported advantages of APRV include sustained alveolar recruitment with improved oxygenation, higher mean airway pressures accomplished with lower Ppeak and Ppl, spontaneous breathing throughout the ventilatory cycle, and decreased use of sedation and neuromuscular blockade in severe ARDS.³⁷ The maintenance of spontaneous breathing may improve \dot{V}/\dot{Q} matching by preferential ventilation of dependent lung regions, and the higher mean airway pressure, relative to Ppeak and Ppl, may limit VILI.

Alveolar recruitment is a pan-inspiratory phenomenon and alveoli that are recruited are more compliant than recruiting or nonrecruited alveoli. With prolonged elevated pressures, APRV likely recruits alveoli, which require a longer inflation with higher threshold opening pressures.^{36,37} Sustained inflation maintains recruitment, decreases shunt and dead space, and employs the more compliant expiratory limb of the pressure-volume (PV) curve. Ventilation is determined by the stored kinetic energy at the high pressure, the intermittent release phase, and is augmented by spontaneous breathing. Although minute ventilation is decreased with this mode of ventilation, ventilation is also improved by a decrease in dead space.

Clinical data are limited but have shown improved oxygenation, less shunt and dead space, as well as decreased need for sedation and neuromuscular blockade.³⁷⁻⁴¹ Data on clinically relevant outcomes, such as mortality rates, mechanical ventilation days, and ICU days, are limited. This mode remains physiologically attractive for its effects on oxygenation and potential to limit VILI, but no specific recommendations can be made, given the lack of good outcome data.

HIGH-FREQUENCY OSCILLATORY VENTILATION

High-frequency oscillatory ventilation (HFOV) is very different from conventional bulk flow ventilation and uses respiratory frequencies much higher and tidal volumes much lower than conventional modes. It is similar to APRV in that it aims to elevate mean airway pressure to maximize recruitment and oxygenation, while limiting Ppeak.⁴² Oxygenated, humidified gas (bias flow) passes in front of an oscillating membrane and generates very small tidal volumes at very high respiratory rates. This is actively driven by a piston pump that oscillates the diaphragm. This produces sinusoidal or somewhat erratic pressure waves that are actively driven in both inspiration and expiration (unique in that expiration is not passively driven by elastic recoil). This component is created by the backward movement of the diaphragm or piston of the oscillator. Resistance valves are used to apply a constant distending airway pressure, over which small tidal volumes are superimposed at a high respiratory frequency; in this fashion, it uncouples, for the most part, oxygenation and ventilation.

Given the fact the tidal volume is often less than anatomic dead space, HFOV relies on gas transport mechanisms much different from those employed by bulk flow ventilation. These mechanisms include some convective gas transport, but also molecular diffusion, pendelluft, coaxial flow, and Taylor dispersion.⁴³

When initiating HFOV, the patient's endotracheal tube should be verified to be patent, as heavy secretions or kinks in the endotracheal tube will significantly harm ventilation.

The mean airway pressure should be set at about 5 cm H₂O higher than that achieved with conventional settings. The bias flow delivers fresh gas into the ventilator circuit at 40 to 60 L/minute and helps maintain mean airway pressure.⁴³ The power control allows adjustment of amplitude (Δ pressure), which is set high enough to elicit vibrations of the patient to the lower abdomen or midhigh. Frequency helps determine ventilation and is set typically at 3 to 5 Hz. It should be noted, however, that at low frequencies, higher tidal volumes and bulk flow can be achieved, which assists in ventilation (and may contribute to VILI). Percentage of I time is set at 33% or 50%, depending on ventilation goals.

This effect would be predicted to be most beneficial when applied early in the course of severe ALI.^{42,44} Recently completed clinical trials of the comparison of HFOV with ARDS net setting standard ventilation in patients at the onset of moderate or severe ARDS showed no benefit of HFOV, and one of the two trials showed increased mortality rate in the HFOV arm.^{44,45} This would imply consideration of HFOV use only as salvage therapy in ARDS. The clinician should note that patients ventilated with HFOV will require heavy sedation or neuromuscular blockade.

EFFORT-ADAPTED MODES OF MECHANICAL VENTILATION

Early mechanical ventilators, such as the CMV mode setting, performed work on the patient and adapted the patient to the ventilator, with complete ventilator and physician control over breath characteristics and delivery. Although this can achieve adequate oxygenation and ventilation, it can come at a great expense to the patient, with side effects to include dyssynchrony, increased work of breathing, respiratory muscle weakness, and increased use of sedative infusions. Advances in ventilator technology, and increased recognition of the side effects of mechanical ventilation, have led to an increased awareness to adapt the ventilator to the patient, using the patient's physiology and demand to assist the respiratory muscles in proportion to effort and need. These effort-adapted modes of mechanical ventilation include proportional assist ventilation (PAV), neurally adjusted ventilatory assist (NAVA), and adaptive support ventilation (ASV).

PAV is a mode of partial support in which ventilator assist is delivered in proportion to patient effort. A defined level of assist, or unloading, relieves the resistive and elastic burden of the respiratory system.^{46,47} The ventilator responds to the *mechanical output* of the patient and will amplify patient effort with a preset proportional amount of pressure support. The theory behind PAV is based on the equation of motion; based on changes in flow and volume, flow-proportional and volume-proportional pressure support is given. A percentage of effort is set by the clinician, and applied airway pressure develops as a function of volume to overcome elastance or a function of flow to overcome resistance.⁴⁶ Reported benefits of PAV include improved synchrony, better physiologic breathing pattern, and improved sleep quality.⁴⁸⁻⁵⁴ A limitation of PAV is that it relies on the mechanical output from the patient, and therefore, continuous knowledge of the elastic and restrictive properties of the patient is a necessity. If PAV incorrectly estimates the

mechanical properties, the ventilator may overassist, causing delayed inspiratory ending (“runaway phenomenon”). This problem has been improved by the development of PAV+ (PAV with load adjustable gain).

NAVA is similar to PAV in that it is also an effort-adapted mode of partial assist. Unlike PAV, which responds to the mechanical output from the patient, NAVA responds to the *neural input* from the electrical activity of the diaphragm (Edi). Pressure is applied in a linear proportion to Edi, and this requires the placement of an esophageal electrode (similar to nasogastric tube placement). The ventilator is triggered based on Edi or conventional signals (whichever comes first), therefore improving synchrony, as the time delay from patient effort to breathe is very brief. In addition, the amount of ventilator assistance varies based on Edi. As such, to achieve greater assistance, the patient must increase Edi. Reported benefits include improved synchrony⁵⁵⁻⁵⁹ and preserved variability in breathing pattern.^{46,60,61} High NAVA levels and high Edi may result in high inspiratory pressures and tidal volume delivery, especially in patients with unstable respiratory patterns or high respiratory drive.^{62,63}

ASV ensures a set target minute ventilation based on measurements of the patient’s E time constant and dynamic compliance, along with preset information of predicted body weight, minimum minute volume limit, and a pressure limit.⁴⁶ The ventilator attempts to minimize the work of breathing by combining the most effective combination of rate and tidal volume, while limiting pressure support. ASV potential benefits include decreased work of breathing and improved patient-ventilator interaction.

Effort-adapted modes of ventilator assist are physiologically attractive, especially considering that most conventional modes of mechanical ventilation are decades old. The decision to use these modes should be tailored to the individual patient. Patients with a high amount of dyssynchronous breaths and iPEEP secondary to obstructive physiology may benefit from a switch to these modes. They do not, however, ameliorate iPEEP, and extrinsic PEEP should be delivered appropriately. In patients who are severely hypoxemic or hemodynamically unstable, these modes should likely be avoided. All require an intact ventilator drive, and ongoing assessments of pulmonary mechanics is a necessity. Finally, the clinician must give up a significant amount of control with these modes of ventilation (which may be unappealing to some practitioners), and outcome data are currently lacking.

POSITIVE END-EXPIRATORY PRESSURE

CPAP maintains airway pressure above atmospheric pressure throughout the respiratory cycle by pressurization of the ventilator circuit. In mechanically ventilated patients, the purpose of CPAP is to achieve therapeutic PEEP in the presence of ALI or pulmonary edema (Fig. 9.7). In these patients PEEP serves to restore functional residual capacity (FRC), reduce IP shunt, shift ventilation to a more compliant portion of the PV curve, and prevent end-expiratory volume loss (derecruitment).⁶⁴ PEEP recruits previously nonaerated lung tissue and homogenizes regional distribution of tidal ventilation. The net effect on gas exchange reflects the balance between

Figure 9.7 A pressure-time waveform in a patient with continuous positive airway pressure (CPAP) without application of pressure support ventilation is demonstrated. The patient is breathing spontaneously at an elevated baseline system pressure. With initiation of inspiration (arrows), pressure becomes more negative (but remains positive), and with expiration, pressure becomes more positive.

recruitment and overdistention. In the setting of obstructive physiology or expiratory flow limitation, PEEP serves less to improve oxygenation, but more to improve patient-ventilator synchrony and triggering.^{27,28,65}

PEEP is not without side effects. Given the heterogeneous distribution of lung injury in ALI/ARDS, PEEP can overdistend more compliant lung units, contributing to VILI.⁶⁶ If PEEP leads to overdistention, it can augment dead space, increase pulmonary vascular resistance, and cause right-sided heart dysfunction. It can also decrease venous return and, in the setting of volume depletion, decrease cardiac output.

The optimal way to set PEEP is debated and controversial, as is the optimal level of PEEP to use.⁶⁷⁻⁸²

See Chapter 11 for a detailed discussion of PEEP application in ARDS.

MONITORING THE VENTILATED PATIENT

HEMODYNAMICS

Positive-pressure ventilation causes predictable physiologic changes and cardiopulmonary function is intimately linked—respiratory function alters cardiovascular function and vice versa.^{83,84} The venous system is a low-pressure reservoir that contains about three fourths of our total blood volume.^{83,85} This can be divided into the stressed and unstressed volume. The stressed volume contributes to the return of blood to the heart. The right ventricle’s main function is to accept venous return and eject the optimal amount of blood into a (usually) highly compliant pulmonary vascular system.⁸⁴⁻⁸⁷ This maintains a low right atrial pressure, thereby maximizing venous return and overall myocardial performance. A positive-pressure breath increases lung volume and increases intrathoracic pressure, which increases juxtacardiac pressure and therefore right atrial pressure. This can decrease venous return and therefore left ventricular preload several cardiac cycles later. At the same time, positive-pressure ventilation decreases left ventricular afterload by increasing the juxtacardiac pressure, therefore assisting ventricular contraction.

With respect to the mechanical ventilator, arterial blood pressure monitoring is commonplace in all intensive care

units (ICUs). Though noninvasive cuff measurements can be adequate, invasive, continuous monitoring is much more informative when ventilator settings are dynamically changing. A fall in blood pressure temporally related to a ventilator change is a fairly specific indicator of a drop in cardiac output.⁸⁵ A narrow pulse pressure may indicate relative hypovolemia, although a widened pulse pressure may point to vasodilation or regurgitant cardiac valve disease. Pulse pressure variation (secondary to previously described heart-lung interactions) in mechanically ventilated patients is also the most accurate predictor of determining preload responsiveness.⁸⁸ Central venous pressure (CVP) is a reflection of right atrial pressure, and normally is low to maximize venous return. Despite the commonality of its use in determining volume status and preload responsiveness, data and physiology have shown that to be inaccurate.⁸⁹ This does not indicate the measurement of CVP is not of value. The absolute value and morphologic appearance (e.g., large v wave) of the CVP tracing can serve as valuable surrogates for right ventricular function, and an inspiratory fall in CVP can indicate preload responsiveness.⁹⁰ There are multiple other hemodynamic variables that could be measured in the mechanically ventilated patient, such as pulmonary artery occlusion pressure and mixed venous oxygenation, and these should be based on individual patient characteristics.

PULSE OXIMETRY

Pulse oximeters determine oxygen saturation by determining arterial blood light absorption at 660 nm and 940 nm wavelengths. The ratio of absorption of these two wavelengths is then calibrated against computer-stored algorithms to determine the oxygen saturation. Pulse oximeters are quite accurate at their upper range, but lose accuracy at lower oxygen saturations, require a good pulsatile signal, and have other limitations. These limitations include hypoperfusion, motion artifact, dyshemoglobinemias, ambient light, certain intravenous dyes, and deeply pigmented skin. Pulse oximetry is virtually ubiquitous in the ICU. Its use includes detection of hypoxemia, monitoring response to ventilator changes (such as PEEP setting), weaning FIO_2 , and as a surrogate for pulmonary gas exchange.⁹¹

END-TIDAL CAPNOGRAPHY

End-tidal capnography (EtCO_2) is a useful way to monitor the concentration of exhaled carbon dioxide (CO_2), plotting it against time. A normal capnogram consists of a low value at baseline during inspiration and while emptying CO_2 -free dead space. This is followed by a steep increase as alveolar units empty CO_2 , and this increases progressively until a plateau is reached. A normal value (e.g., when ventilation and perfusion are matched) is about 5 mm Hg less than the PaCO_2 , and a normal shape consists of a low baseline, steep ascending portion, plateau, and steep decline. The $\text{EtCO}_2/\text{PaCO}_2$ gap can widen in patients with altered \dot{V}/\dot{Q} relationships or changes in cardiac output; the morphologic pattern of the waveform can be altered in patients with endobronchial intubation, expiratory flow limitation, and ventilator dyssynchrony.

VENTILATOR WAVEFORMS

Modern ventilators allow continuous monitoring of pressure, volume, and flow waveforms, all of which are plotted against time. They are useful in readily identifying the mode of mechanical ventilation being used, as well as identifying physiologic abnormalities. Examination of the flow waveform can allow detection of iPEEP. A ripple-like waveform can indicate water or secretion buildup in the ventilator circuit. A prolonged expiratory flow pattern can indicate expiratory flow limitation. The pressure waveform allows calculation of compliance of the respiratory system, and an estimation of transalveolar pressure with an end-inspiratory hold maneuver to calculate plateau pressure. An initial overshoot in the pressure waveform may signal high patient effort or an overshoot on ramp speed. An upward inflection at the end of the pressure waveform could signal overdistention, and a dip in an otherwise square pressure waveform can signal patient effort and dyssynchrony.

MAINTAINING SUPPORT OF THE VENTILATED PATIENT

SEDATION AND ANALGESIA

Critically ill patients who are mechanically ventilated often require sedative and analgesic drugs, and pain is common among ICU patients.⁹² The ideal sedative and analgesic regimen would provide adequate sedation and pain control, rapid onset of action, rapid recovery after discontinuation, minimal systemic accumulation, and minimal adverse effects—without raising health care costs.⁹³ The primary aim of these medications is to reduce the physiologic stress of respiratory failure and to improve the tolerance of mechanical ventilation. As more patients survive acute illness, the importance of goal-oriented sedation and analgesia has emerged, and the deleterious side effects of these medications is evident.⁹⁴

Historically, mechanically ventilated patients have been treated with continuous infusions of benzodiazepines, opiates, and propofol.⁹⁵⁻⁹⁷ Unfortunately, emerging data point to increased side effects associated with these medications, such as delirium, increased mechanical ventilation days, increased lengths of hospital stay, and higher mortality rate.^{94,98,99} This has prompted interest in novel regimens with agents such as dexmedetomidine, an α_2 -agonist with sedative and analgesic properties. Data have shown that dexmedetomidine use is associated with a reduction in delirium, improved cognitive function, and decrease in mechanical ventilation days.¹⁰⁰⁻¹⁰⁴

Regardless of the sedation regimen chosen, the mechanically ventilated patient should have sedation and analgesia titrated to a validated scale, such as the Richmond Agitation Sedation Scale, and delirium should be monitored at least daily, also with a validated scale (Confusion Assessment Method for the ICU [CAM-ICU]). All patients should be assessed daily for readiness to be liberated from the ventilator (spontaneous awakening trial [SAT]), and this should be paired with a spontaneous breathing trial (SBT).

POSITIONING

There is no optimal position for an individual patient and certainly no evidence-based gold standard. Predictable physiologic changes occur in patients when placed in the supine position, including reduced FRC, alteration in pleural pressure, reduced lung compliance, and change in \dot{V}/\dot{Q} matching. The supine position should be avoided, as it is a risk factor for ventilator-associated pneumonia (VAP).^{105,106} In patients with unilateral lung injury, the “good side” should be placed in the dependent position to optimize \dot{V}/\dot{Q} match. Patients with severe hypoxemia ($\text{PaO}_2/\text{FiO}_2$ ratio < 100) should be considered for prone positioning early in the course of ALI, as this will likely improve oxygenation and may offer survival benefit in this patient cohort.¹⁰⁷

SECRETION CLEARANCE

Secretion clearance is impaired in the mechanically ventilated patient owing to decreased mucociliary activity and inability to cough effectively. Removal of oral and tracheobronchial secretions is commonplace and standard care of the mechanically ventilated patient. Because of insufficient data and complications, scheduled and routine suctioning should be avoided, but the decision is based on patient assessment. The use of closed-circuit catheters is now commonplace, but data are conflicting with regard to patient benefit when compared to open-circuit catheters. Prior to the suctioning procedure, the caregiver should be aware of the potential for complications, such as hypoxia, airway trauma, and cardiac arrhythmias.

WEANING FROM MECHANICAL VENTILATION

Shortly after a patient is endotracheally intubated to initiate mechanical ventilation, thoughts should turn toward liberation from the ventilator. The withdrawal of mechanical support is a continuum from intubation until hospital discharge.^{108,109} Depending on severity of illness, patient comorbid conditions, and critical care treatments needed, the timing of this may range from hours to weeks or months. There are several evidence-based guiding principles that shorten mechanical ventilation days across a broad cohort of critically ill patients.

The first step (and perhaps most important) in liberation from the ventilator is the targeted use of sedation, limitation of sedative and opioid infusions, and the monitoring for and aggressive treatment of delirium.⁹⁴ Patients should also undergo daily interruption of sedative medications (SAT), which has been shown to decrease ventilator days and ICU length of stay.¹¹⁰ After awakening, the patient should be assessed for readiness to wean. The literature abounds with weaning predictors, all of which have modest sensitivity and specificity, including the frequency/tidal volume ratio.¹⁰⁹ Given this, as opposed to weaning predictors, the patient should undergo an SBT based on common sense, overall clinical trajectory, lack of hypoxia, and hemodynamic stability. The SAT should be paired with an SBT, as the SAT-SBT pairing decreases ventilator days, shortens ICU and hospital length of stay, and improves mortality rate.¹¹¹ An SBT can

be conducted unassisted through a T-piece, on low-level PSV, or on CPAP, once or multiple times a day, and from 30 to 120 minutes; SIMV weaning is not recommended.¹¹²⁻¹¹⁷ If a patient fails an SBT, a reason for that failure should be sought and corrected. This could include sedation, weakness, delirium, respiratory muscle fatigue, or left ventricular dysfunction. Also, after failing an SBT the patient should be placed immediately on comfortable full mechanical support, as delaying this and prolonging the SBT to the point of respiratory muscle exhaustion can delay extubation. After passing an SBT, the patient should be extubated unless a reason exists to leave the endotracheal tube in place (e.g., no cough reflex and heavy pulmonary secretions). The ability to predict successful extubation is challenging, and if the clinician never experiences a reintubation, he or she is likely not extubating patients based on the best available evidence.

COMPLICATIONS OF MECHANICAL VENTILATION

HEMODYNAMICS

Blood pressure is simply the product of cardiac output and systemic vascular resistance ($\text{BP} = \text{CO} \times \text{SVR}$). Although the transition of positive-pressure ventilation is associated with a predictable set of physiologic responses, the overall hemodynamic response is largely a consequence of underlying patient comorbid conditions (such as left ventricular dysfunction) and preload status. Immediately after endotracheal intubation, worsening hemodynamics are usually secondary to a decrease in preload, as right atrial pressure will increase, or a drop in arteriolar tone from sedation and analgesia. Any change in hemodynamics in the mechanically ventilated patient should prompt a thorough and almost algorithmic evaluation for potential causes.

VENTILATOR-INDUCED LUNG INJURY

Mechanical ventilation can be a lifesaving intervention. However, it has great potential for harm, and the clinician's focus should extend beyond normalization of gas exchange to providing safe and physiologically sound mechanical ventilation. Perhaps nowhere is this demonstrated more significantly than with the concept of VILI. Most patients with ALI do not die of hypoxia, but rather multiple organ dysfunction syndrome (MODS).¹¹⁸⁻¹²¹ Applied airway pressures in patients with ALI distribute in a heterogeneous fashion, leaving more compliant lung units overdistended, and others collapsed and nonrecruited. Respiratory system compliance is related to the amount of normally aerated lung tissue that remains, the so-called baby lung.¹²² This heterogeneity leads to a maldistribution of ventilation, with some alveoli overdistended, others collapsed throughout the respiratory cycle, and others cyclically opening and closing. VILI is a spectrum, classically defined as barotrauma, atelectrauma, and volutrauma (stretch injury).¹²³ All of these can lead to biotrauma, or the decompartmentalization of the inflammatory response secondary to increased alveolar epithelial-capillary endothelial permeability. This results in the release of biologic inflammatory mediators and the

spread of injury to distant organs, causing MODS and death. VILI is much more complex than the preceding definitions and involves tissue stress and strain modifiers, complex molecular mechanisms, as well as gene activation and up-regulation.^{124,125}

Human studies support the concept of VILI and the importance of a protective ventilation strategy with low tidal volumes and the use of PEEP. Low tidal volume ventilation is the only intervention shown to consistently improve outcome in ALI, and support for protective lung ventilation to decrease VILI from several well-conducted clinical trials exists.^{71,72,126} This includes data showing a decrease in inflammatory mediators in patients ventilated with a protective lung strategy. In the absence of a patient-specific factor to suggest otherwise, a protective ventilation strategy, consisting of low tidal volume ventilation, PEEP setting, and limitation of plateau pressure, should be attempted at all times. Emerging data suggest that these strategies should be employed not only in patients with ALI, but in all patients receiving mechanical ventilation, especially those with known risk factors for the development of ALI.¹²⁷

VENTILATOR-ASSOCIATED PNEUMONIA

One of the most frequent complications of mechanical ventilation is the development of VAP.¹²⁸⁻¹³⁹ VAP is discussed in Chapter 42.

GASTROINTESTINAL BLEEDING

Mechanical ventilation is a risk factor for gastrointestinal bleeding secondary to stress ulceration, trauma (especially traumatic brain injury), and major burns. Mechanical ventilation for longer than 48 hours is regarded as the most frequent risk factor.¹⁴⁰ The most effective treatment of stress ulceration is prevention. H₂-receptor antagonists and proton pump inhibitors have been shown to reduce the incidence of clinically important bleeding when compared to sucralfate and are considered the first-line therapy among many clinicians.¹⁴¹⁻¹⁴⁵

VENOUS THROMBOEMBOLISM

Venous thromboembolism (VTE) refers to the development of deep venous thrombosis (DVT) or pulmonary embolism (PE) in the critically ill patient. Patients in whom DVT develops have worse clinical outcomes, including prolonged mechanical ventilation.¹⁴⁶ Furthermore, VTE is common and frequently asymptomatic in mechanically ventilated patients. Given the adverse clinical outcomes associated with VTE, thromboprophylaxis with low-molecular-weight heparin or unfractionated heparin, both administered subcutaneously, should be given unless contraindicated.¹⁴⁷⁻¹⁴⁹

NONINVASIVE POSITIVE-PRESSURE VENTILATION

Noninvasive positive-pressure ventilation (NIPPV) offers the potential to provide ventilatory assistance without an invasive artificial airway. NIPPV may be accomplished using a facemask or nasal mask fitted to the face and connected

through standard ventilator tubing to either a standard mechanical ventilator or smaller ventilators made specifically to deliver noninvasive mechanical ventilation.

In patients with COPD and type II respiratory failure, NIPPV reduces dyspnea, decreases intubation rates, and improves mortality rates.¹⁵⁰⁻¹⁵² Similarly, in patients with cardiogenic pulmonary edema, NIPPV decreases intubation rates and improves survival.^{152,153} NIPPV may also serve a critical role in decreasing mechanical ventilation days and improving weaning success, especially in patients with COPD recovering from type II respiratory failure.^{154,155} Finally, immunocompromised patients, especially those with hematologic malignancies, should be considered for NIPPV.¹⁵⁶ Prior to initiation of NIPPV, the patient should be assessed for an adequate mental status for airway protection, hemodynamic stability, and lack of excessive secretions.

KEY POINTS

- High-pressure alarms are triggered by patient factors (such as decreased compliance and increased resistance of the respiratory system) or by ventilator circuit malfunction (obstruction or kinking of the endotracheal tube).
- Low-pressure alarms are generally secondary to a leak in the system (ventilator circuit, endotracheal tube or cuff) or patient (large pressure loss from a bronchopleural fistula).
- Automatic tube compensation (ATC) compensates for endotracheal tube resistance via closed-loop control of calculated tracheal pressure.
- The breath generated by a mechanical ventilator can be separated into four phases: triggering, inspiration, cycling, expiration.
- With pressure control and pressure support breaths the pattern of inspiratory flow is a natural decelerating pattern as the pressure gradient for flow decreases as pressure rises in the patient's lungs.
- In AC ventilation, a mandatory number of breaths are set and delivered with a set pressure or flow (assisted or unassisted), and if the patient's respiratory rate is higher than this backup setting (rate) additional assisted breaths to the preset pressure or flow are delivered. The target variable can be pressure (PC/AC) or volume (VC/AC).
- With SIMV, the ventilator delivers a mandatory number of breaths with a set pressure or flow (assisted or unassisted), similar to AC ventilation. However, spontaneous breaths are delivered upon patient triggering during a timing window created around the delivery of mandatory breaths. These spontaneous breaths can be totally driven by patient effort or pressure enhanced as pressure-controlled/flow-cycled (PS) breaths.
- Although outcome data are lacking compared to conventional ventilation using protective lung

Continued on following page

KEY POINTS (Continued)

strategies, the reported advantages of APRV include sustained alveolar recruitment with improved oxygenation, higher mean airway pressures accomplished with lower P_{peak} and P_{pl}, spontaneous breathing throughout the ventilatory cycle, and decreased use of sedation and neuromuscular blockade in severe ARDS.³⁷

- PAV is a mode of partial support in which ventilator assist is delivered in proportion to patient effort.
- NAVA is similar to PAV in that it is also an effort-adapted mode of partial assist. Unlike PAV, which responds to the mechanical output from the patient, NAVA responds to the neural input from the Edi. Pressure is applied in a linear proportion to Edi, and this requires the placement of an esophageal electrode (similar to nasogastric tube placement).

Periextubation Phase

Positive-pressure ventilators have been in widespread clinical use for more than 4 decades. Our understanding of respiratory muscle function and ventilatory failure has undergone major revision over that period, helping to gear equipment and treatment strategies more effectively to patient requirements. Some of the more important advances in this area concern the interactions of patients having obstructive pulmonary disease (airflow obstruction [AO]) with the mechanical ventilator. Others concern physiologic principles important in withdrawing machine support from ventilator-dependent patients, many of whom have chronic obstructive pulmonary disease (COPD) or asthma. With these advances in mind, the purpose of this chapter is to provide an updated physiologic background for understanding mechanical ventilation in patients with AO, as well as to review selected aspects of this problem that are frequently overlooked and, though noteworthy, may be unfamiliar to many practitioners. Noninvasive ventilation, a modality of immense value in the treatment of alert patients with moderately severe obstructive illnesses, will not be extensively addressed here, as it is covered in other chapters of this text.

SPECIAL CHALLENGES OF PATIENTS WITH SEVERE AIRFLOW OBSTRUCTION

By assuming a major portion of the ventilatory workload, mechanical ventilation affords the opportunity to rest the respiratory muscles while maintaining pH homeostasis and oxygenation, thereby averting progressive ventilatory failure, respiratory arrest, or both. Unfortunately, these benefits are not cost-free—mechanical ventilation is expensive, uncomfortable, and inherently hazardous; few would dispute the desirability of avoiding the need for its implementation or of accelerating the process of its withdrawal. Although deceptively simple in concept, the management of patients with AO who require mechanical support often proves to be a rather complex clinical undertaking. To manage respiratory failure effectively in patients with severe AO, it is important to understand their distinctive problems. Patients with severe AO may be characterized by a number of salient clinical features. Paramount among these are increased work of breathing and mechanical compromise of the ventilatory pump that must contend with it. Such patients are

also distinguished by their susceptibility to the hazards of machine support.

INCREASED WORK OF BREATHING

The mechanical breathing workload during passive ventilation can be quantified as the product of mean inflation pressure and minute ventilation. The mean inflation pressure (P_m) is approximated in a modification of the equation of motion of the respiratory system:

$$P_m = R(\text{flow}) + V_T/2C + \text{PEEPi}$$

In this equation R = resistance; V_T is tidal volume; C is respiratory system compliance (the inverse of elastance); and PEEPi is auto-PEEP, the positive end-expiratory alveolar pressure in excess of set PEEP because of dynamic hyperinflation (Fig. 10.1).

Increased resistance to airflow is responsible (directly or indirectly) for many of the physiologic disturbances that typify this disease. Flow resistance, an important determinant of P_m , is increased by structural and functional narrowing of the airway. Structural changes include a reduced number of airway channels, as well as narrowed cross-sectional airway caliber. In this already narrowed tapering network of tubes, the additional reduction of airway caliber caused by mucosal edema, functional compression, increased bronchomotor tone, or secretion accumulation noticeably increases the work of breathing because resistance relates linearly to the airway length but inversely to the fourth power of airway radius. For similar reasons, resistance within these critically narrowed airways is highly volume dependent, so that loss of lung volume is accompanied by loss of elastic recoil tension, reduction of cross-sectional area, tendency for expiratory airway collapse, and major increases in the frictional workload.^{1,2}

Although each factor just enumerated contributes to AO, functional compression of the airway during exhalation is of overriding importance in many patients with components of emphysema or vigorous expiratory effort. Loss of elastic recoil encourages collapse of these narrowed bronchi as their transluminal distending pressure gradients decline (or reverse) during the course of exhalation. In most patients who require mechanical ventilatory support, dynamic airway

Figure 10.1 Depiction of the elements of the inspiratory equation of motion and their associated work of breathing. Stippled area is resistive work, and striped areas represent the elastic work associated with tidal volume and auto-positive end-expiratory pressure, respectively.

collapse occurs even during tidal breathing, so the average airway resistance is often several times higher during exhalation than during the inspiratory phase of ventilation. This compressive mechanism underlies the phenomenon of air trapping and such hyperinflation-related consequences as loss of inspiratory power and reduced compliance of the respiratory system.

DYNAMIC HYPERINFLATION (AIR TRAPPING)

Expiration is normally a passive process that uses elastic energy stored during inflation to drive expiratory airflow. If the energy potential stored during inflation is insufficient to return the system to a relaxed equilibrium before the next inspiration begins, flow continues throughout expiration and alveolar pressure remains positive at end expiration, exceeding the clinician-selected PEEP value (Fig. 10.2).³⁻⁹ This positive distending pressure within the alveoli increases the driving pressure for expiratory airflow and increases lung volume, thereby helping to overcome airflow resistance. Unfortunately, such hyperinflation also places the expiratory musculature at a mechanical disadvantage. Furthermore, because the hyperinflating end-expiratory alveolar pressure encourages deflation, it must first be counterbalanced by positive pressure applied to the central airway or by negative pleural pressure before inspiration can begin.^{10,11} Thus PEEPi adds to the other components of the equation of motion to elevate the mean inflation pressure and inspiratory work of breathing. The process of air trapping contributes to an increase in the respiratory work of breathing in at least two other ways. Hyperinflation drives the respiratory system upward toward the least compliant portion of the pressure-volume relationship, incurring increased elastic work per liter of ventilation (see Fig. 10.1). At these higher volumes the lung approaches its elastic limit as the recoil tension of the distended rib cage becomes *expiratory* rather than *inspiratory* in nature. Finally,

Figure 10.2 The auto-positive end-expiratory pressure (PEEP) effect. Auto-PEEP is the positive flow driving the difference between alveolar and airway opening pressures at end expiration. As depicted here, it can vary widely from site to site within the lung.

hyperinflation tends to convert more of the well-perfused (“zone 3”) lung into less-well-perfused tissue, thereby increasing ventilatory deadspace and the minute ventilation requirement.

Generally, the resistance increase in patients with chronic AO and many of those with severe asthma concentrates within small airways.¹ Yet for certain asthmatic patients, the central airways and larynx contribute impressively to total resistance, accounting for the helpfulness of helium-oxygen (heliox) mixtures in some (but not all) patients during exacerbated asthma.¹² According to some reports, heliox helps to reduce air trapping in patients with COPD as well. Although there is some concern regarding the generalizability and accuracy of such observations, several mechanisms can be invoked, even if the *primary* site of expiratory obstruction is too peripheral for helium to reduce resistance there. These mechanisms include reduced inspiratory turbulence, faster expiratory flow in non-flow-limited channels with increased wave speed, modestly decreased CO₂ production, and perhaps reduced associated gas trapping.

Of note, dynamically positive end-expiratory alveolar pressure can also exist without hyperinflation, provided that airway collapse does not occur. In these instances expiratory muscle contraction increases pleural pressure, alveolar pressure, and the speed of expiratory airflow, obviating the need for hyperinflation to complete exhalation in the allotted time. Such mechanisms are employed by normal subjects during heavy exercise or when faced with major respiratory workloads. Indeed, many untrained normal subjects expire to positions below the equilibrium point of the respiratory system when exposed to PEEP. In this way the respiratory muscles can begin contraction from a mechanically advantageous position, and the expiratory muscles can share in the ventilatory work. Using this strategy, PEEP actually provides a boost to *inspiration*, experienced early in the cycle when the *expiratory* muscles relax. This “work-sharing” strategy, although effective for a normal individual, cannot be implemented by patients who experience dynamic airway collapse during tidal breathing. Because forceful expiratory efforts succeed not only in raising alveolar pressure but also in intensifying dynamic airway collapse, flow rate is determined strictly by lung volume and is not accelerated by expiratory muscle activity after the first third of expiration has been completed.

When dynamic collapse occurs during tidal respiration and breathing requirements are high, there is little alternative to hyperinflation, CO₂ retention, or both. At the chosen level of minute ventilation, maintaining the lower lung volume may be either too energy costly or physically impossible. For this reason, many patients with severe obstruction do not or cannot decrease their lung volumes when recumbent. Such considerations may help to explain the dyspnea experienced by most patients with severe AO on assuming horizontal positions. For the same recumbent angle, the lateral position allows slightly more decompression than does the supine position because lung volume influences airway caliber, airway resistance, and tendency for collapse as the lung deflates.¹³ Patients with obesity have a lower resting lung volume and therefore exhibit higher airway resistance and tendency for dependent atelectasis and symptoms when airways are narrowed by bronchoconstriction or

disease. Likewise, patients with acute respiratory distress syndrome have higher than normal airway resistance in dependent zones.

In fact, the distribution of gas trapping varies regionally throughout any diseased lung, depending on the local mechanical properties of the airways. Therefore, at the end of the expiratory cycle some zones remain patent, and some have sealed much earlier in the deflation cycle (see Fig. 10.2). Consequently, the end-expiratory value of auto-PEEP detected at the airway opening may not reflect the magnitude of gas trapping.¹⁴ Clues to the presence of regional closure are often seen when the airway is occluded at end expiration; the auto-PEEP value shows an atypically slow rise to its final value as quasi-occluded small airways decompress into the common airway. In such cases, PEEP often eliminates this characteristic. During volume-controlled ventilation, plateau pressure tracks hyperinflation more reliably than direct measurements of PEEPi.

In some patients, especially those who passively receive ventilatory support, the problems presented by air trapping and dynamic hyperinflation are as much cardiovascular as pulmonary in nature. A relatively high fraction of the resulting positive alveolar pressure is transmitted to the pleural space, where it impedes venous return and confuses interpretation of hemodynamic pressure measurements made with pulmonary artery catheters (Fig. 10.3). Lung distention also adds to pulmonary vascular resistance, exacerbating the tendencies of patients with *cor pulmonale* toward low cardiac output and hypotension. Marked respiratory variation of systolic and pulse pressures during passive inflation indicates phasically adverse cardiac loading and strongly implies the possibility of dynamic hyperinflation (Fig. 10.4).

INCREASED MINUTE VENTILATION REQUIREMENT

Ventilation-perfusion (\dot{V}/\dot{Q}) mismatching is widespread in patients with severe AO, reducing the efficiency of carbon dioxide elimination.¹ It is not uncommon for the resting minute ventilation requirement to exceed 12 L per minute (twice the normal value) in patients with exacerbated

Figure 10.3 The hemodynamic impact of auto-PEEP (positive end-expiratory pressure) in a passively ventilated patient with severe airflow obstruction. A 40-second disconnection of the ventilator was associated with rising blood pressure and cardiac output despite a falling pulmonary artery wedge pressure.

Figure 10.4 Marked respiratory variation of systemic arterial blood pressure, indicative of the relative variation in cardiac loading conditions associated with dynamic hyperinflation. PP, pulse pressure. (From Michard F, Teboul J-L: Using heart-lung interactions to assess fluid responsiveness during mechanical ventilation. *Crit Care* 2000;4:282-289.)

asthma or extensive emphysema and strong chemical drives to breathe. Not only do such increases in ventilation requirement act as a linear cofactor in the work of the breathing equation already discussed, but the high minute ventilation requirement itself increases most components of inspiratory pressure: flow, elastance (the reciprocal of compliance), tidal volume, and auto-PEEP. It is not surprising, therefore, that enormous increases in the oxygen consumption rate of the ventilatory muscles have been observed in patients with obstructive lung disease. During exacerbations, the oxygen consumed by ventilation and the metabolic demands associated with heightened vigilance, agitation, or anxiety may double the total body oxygen consumption observed during fully supported breathing. The prevalent combination of impaired \dot{V}/\dot{Q} matching, hypoventilation, and diffusion impairment result in arterial oxygen desaturation that generally responds well to modest supplementation of inspired oxygen.

REDUCED MECHANICAL EFFICIENCY

In patients with exacerbated COPD or decompensated asthma, the oxygen consumed in the ventilatory task is disproportionate to the amount of mechanical work actually performed. The muscles of the hyperinflated ventilatory system are inefficiently aligned, force-length relationships of the shortened end-inspiratory fibers are suboptimal, and normally efficient coordination among the various muscles of the ventilatory group is often disrupted.¹⁴⁻¹⁶ The energy cost of breathing, therefore, is greatly increased for the pressure and mechanical work actually generated by the breathing effort.

PROBLEMS AND HAZARDS OF VENTILATION WITH POSITIVE PRESSURE

Patients with AO who require mechanical ventilation present special challenges to the clinician for yet another reason: an unusual predisposition to its adverse consequences that are only loosely related to the airflow resistance. For reasons that are not entirely clear, patients with COPD have been reported to have an increased incidence of gastrointestinal ulceration and bleeding, especially during stress periods. This tendency is accentuated to an important degree by poor nutrition, stress, and the therapeutic use of high-dose corticosteroids. In modern intensive care unit practice, the incidence of ulceration has been greatly attenuated by the use of proton pump inhibitors and other means of acid suppression.

Even when able to cough with maximal force, patients with severe AO have difficulty in clearing contaminated secretions from the central and peripheral airways, predisposing to bronchial and lung infections. This tendency is accentuated when the airway is intubated or when non-invasive ventilation is provided with poorly humidified gas mixtures. These interventions accentuate the impediment to coughing efficiency, may encourage secretion thickening, and promote entry of contaminated secretions from the upper airway. In conjunction with mucus plugging, air trapping, and the tendency toward parenchymal infections, markedly inhomogeneous ventilation predisposes the ventilated patient with severe AO to the varied forms of barotrauma—pneumomediastinum, subcutaneous emphysema, and tension pneumothorax. Because the lungs cannot collapse, even a small pneumothorax in a ventilated patient with severe AO can rapidly develop a tension component, leading to ventilatory and circulatory compromise.

The hemodynamic sensitivity to positive-pressure ventilation of patients with AO arises for several reasons. The overexpanded lungs press outward on the chest wall, raising intrapleural pressure. When breathing efforts are silenced, as they are immediately after sedation and intubation, mean intrathoracic pressure abruptly changes from modestly negative to markedly positive. Increased pleural pressure raises the right atrial back-pressure to venous return. Simultaneously, increased peripheral vascular capacitance (caused in part by drug effects) and reduced peripheral vascular tone limit the rise in mean systemic pressure, the upstream driver of venous return. Blood pressure routinely falls, and cardiac output falls disproportionately to oxygen demand. Absolute values of measured central vascular pressures (central venous and wedge pressures) may therefore be misleadingly high and do not reflect intravascular filling and preload adequacy.⁷ Marked respiratory variation of systolic and pulse pressures with the ventilatory cycle (“paradox”) is a hemodynamic marker of relative hypovolemia caused by such mechanisms (see Fig. 10.4). Depending on choice of tidal volume, backup frequency, and set (and auto) PEEP, the afterload to right ventricular ejection may rise with any further lung expansion, whereas the tendency for alveolar deadspace creation is accentuated. Consequently, great care must be taken not to ventilate excessively and to provide adequate intravenous fluid support during this period. This

advice pertains especially to patients with AO who require cardiac resuscitation.¹⁷

INTERACTIONS OF PRESSURE-TARGETED MODES WITH AUTO-PEEP

Pressure-targeted modes of ventilation, exemplified by pressure control, airway pressure release ventilation (APRV), and pressure support, have become increasingly popular to employ in the care of intubated patients, as well as in those receiving noninvasive ventilation by facemask. Because the development of auto-PEEP reduces the pressure difference between airway opening and alveolus that drives inspiration, it has a powerful influence on ventilation efficacy (Fig. 10.5). As already described, auto-PEEP varies not only with airway mechanics but also with the pattern of breathing and

Figure 10.5 Interaction of alveolar (red line) and applied airway (fine line) pressures in a patient ventilated with pressure-targeted ventilation. Auto-PEEP diminishes the driving pressure of the subsequent ventilatory cycle.

minute ventilation. For a fixed value of applied airway pressure, inspiratory tidal volume in patients with AO will be more sensitive to the frequency and the inspiratory time fraction (an expression of the inspiratory-to-expiratory [I:E] ratio) than are normal subjects or those with restrictive disease¹⁸ (Fig. 10.6). Faster breathing frequencies, for example, allow auto-PEEP to build, and this auto-PEEP must first be counterbalanced for inspiratory airflow to begin. If the patient is passive or the amount of inspiratory muscle force remains constant, delivered tidal volume falls as the auto-PEEP builds.

This auto-PEEP/driving pressure interaction may result in an intriguing phenomenon resembling chaotic respiration during noninvasive ventilation with a leaky mask interface.¹⁹ The coupled PEEPi and tidal volume form a “feed-forward” system in which a building auto-PEEP of one cycle adversely influences the tidal volume of the next one. But this smaller tidal volume also reduces the auto-PEEP that follows that restricted cycle, which in turn allows the subsequent breath—the third in the cycle—to have a larger effective driving pressure and tidal volume, and the cycling variation continues. This may account for some of the wide variability in breathing rhythm often observed in these patients.²⁰ If the mask leak volume is a function of the I:E ratio, it can be shown mathematically and experimentally that fractal and chaotic tidal volume delivery may occur, even when the patient’s effort and mechanics remain unchanged (Fig. 10.7).¹⁹ The consequences for comfort and sleep efficiency are likely to be significant, but clinical data are lacking on these issues at this time.

PRINCIPLES OF MANAGING THE VENTILATED PATIENT WITH SEVERE AIRFLOW OBSTRUCTION

Most patients hospitalized with exacerbations of asthma or COPD can be managed effectively by regimens that incorporate aggressive secretion clearance techniques,

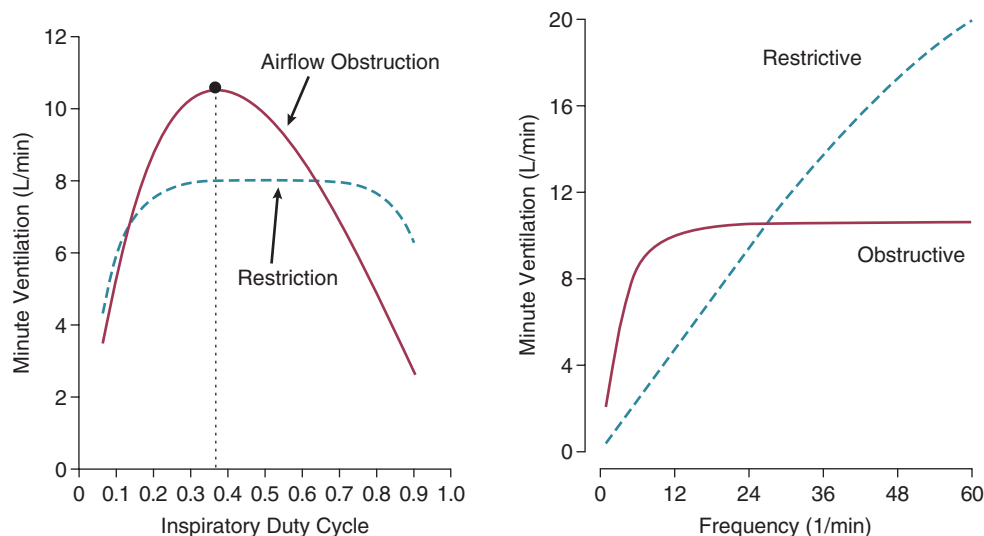

Figure 10.6 Relative sensitivity of patients with airflow obstruction to the settings of frequency and inspiratory time fraction for a fixed pressure target in pressure-controlled ventilation. This sensitivity is induced primarily by the impact of these settings on auto-PEEP (positive end-expiratory pressure).

Figure 10.7 Theoretical behavior of tidal volume in response to pressure support by mask ventilation in a patient experiencing auto-PEEP (positive end-expiratory pressure). At a certain critical value of mask leak, there is wide cycle-to-cycle variation in tidal volume despite unchanging levels of pressure support and patient effort. Near “chaotic” behavior is a consequence of auto-PEEP. (Data from Hotchkiss JR, Adams AB, Dries DJ, et al: Dynamic behavior during noninvasive ventilation. Chaotic support? *Am J Resp Crit Care Med* 2001;163: 374-378.)

antibiotics, corticosteroids, intensified bronchodilators, hydration, cardiovascular support, secretion lubricants (e.g., guaifenesin), and supplemental oxygen. Noninvasive ventilation often helps as a temporizing measure for those with disease of *mild-moderate* severity, especially when cough is adequate to clear airway secretions and the patient is fully alert and accepting of a full facemask.²¹⁻²⁶ Only a minority of such patients treated in this way need translaryngeal intubation and institution of mechanical ventilatory support unless the problem is complicated by coexisting cardiovascular, infectious, or neuromuscular problems. When mechanical ventilation is required, however, the rationale underlying certain key management principles can easily be understood against a background of the physiologic derangements already described. These principles are as follows: (1) provide adequate support for muscle rest at adequate PaO_2 and pH; (2) do not overventilate; (3) minimize the minute ventilation requirement; (4) minimize risk of barotrauma; (5) maintain adequate bronchial hygiene; (6) prevent panic reactions; (7) establish appropriate nutrition. Each principle will be discussed in more detail:

Principle 1: Provide adequate support to rest the ventilatory muscles, while avoiding hypoxemia and profound acidemia.

Poised on the edge of decompensation, the ventilatory muscles must be rested adequately before withdrawal of machine support can be considered. Rest may allow recovery of energy reserves and restore the balance between ventilatory capability and demand. Indeed, benefits may accrue to muscle rest, even when it occurs intermittently on a chronic basis. Sufficient oxygen and mechanical support must be provided to achieve this goal, to permit restorative sleep, and to avoid significant hypoxemia (arterial oxygen saturation < 85%) and acidemia (pH < 7.2)—derangements that increase pulmonary vascular resistance; stimulate vigorous breathing; and inhibit mental, cardiac, and skeletal muscle functions.

Principle 2: Do not overventilate.

Profound respiratory acidosis and hypoxemia accentuate pulmonary hypertension, impair the right ventricle, and should be reversed. Nevertheless, although it is important to provide adequate ventilation and to reverse

hypoxemia, overventilation is detrimental on several counts. Rapid reduction in the alveolar CO_2 tension tends to cause bronchoconstriction and impair neuromuscular and cardiovascular function. Furthermore, excess ventilation exacerbates dynamic hyperinflation and auto-PEEP, whereas moderate Paco_2 elevations are generally well tolerated.²⁷ Generally, it is a mistake to depress the Paco_2 below the level that the patient chronically maintains. Such a strategy may temporarily reset chemical drives, effectively increasing respiratory workload intensity once spontaneous breathing resumes. If Paco_2 falls sufficiently, the patient will not maintain unassisted breathing without intolerable effort, potentially delaying discontinuation of mechanical breathing assistance.

Principle 3: Minimize minute ventilation requirement.

Because hyperinflation, mean inflation pressure, and the adverse cardiovascular consequences of mechanical ventilation are intimately linked to the minute ventilation requirement, ventilatory deadspace and CO_2 output must be minimized and both metabolic acidosis and iatrogenic hyperventilation avoided or addressed.

Principle 4: Minimize the risk of barotrauma.

The predisposition of patients with severe AO to barotrauma must be combated by intelligent choices for tidal volume, ventilation frequency, PEEP, and machine settings of trigger sensitivity and flow. Reduction of the minute ventilation requirement decreases the mean or peak alveolar pressures, or both, reducing the incidence of barotrauma. The relative contributions of mean alveolar pressure, PEEP, dynamic cycling pressure, and peak static (plateau) ventilatory pressure to the risk of barotrauma are not clear. Based on epidemiologic evidence, however, peak airway inflation pressures in a passively inflated lung should be kept below 40 cm H_2O whenever possible. Selecting a tidal volume at the low end of the recommended range (6 to 8 mL/kg of ideal body weight) is probably best. The question of optimal flow setting is of no small importance: auto-PEEP and mean alveolar pressure are reduced by selection of relatively rapid flow settings when minute ventilation is high. Overall ventilation-perfusion matching may improve as well. Higher peak *dynamic* airway pressures engendered

by these rapid flows are not entirely without risk, however; units served by low resistance pathways are in jeopardy from associated overdilation. For the same tidal inspiratory time, a constant (“square”) flow waveform often serves better than a decelerating one. The risk of barotrauma can also be minimized by maintaining the lungs free of infection and the airways clear of secretions.

Principle 5: Maintain effective bronchial hygiene.

Secretion retention may dramatically increase airflow resistance and effectively seal off entire banks of functional alveoli, preventing their participation in ventilation. Thickened central airway secretions are a particular risk during mechanical ventilation, whether invasive or noninvasive (Fig. 10.8).²⁸ Apart from raising the end-inspiratory pressure, the resulting dynamic hyperinflation can detrimentally affect cardiovascular function, work of breathing, and ventilatory capability. In addition

A

B

Figure 10.8 A, Central airway mucus retained in a ventilated patient with severe airflow obstruction. B, The resulting inverted plateau and stutter step deformations of the airway pressure and flow tracings during controlled, volume-cycled ventilation. (From Zamanian M, Marini JJ: Pressure-flow signatures of central-airway mucus plugging. *Crit Care Med* 2006;34:223-226.)

to effective suctioning, bronchodilators, adequate hydration, corticosteroids, mucolytics, mucolubricants, and infection control, frequent repositioning, mobilization, and physiotherapy are fundamental to secretion management. Percussive ventilation or vibro-percussive vest treatments often complement mobilization effectively when tolerated. Tracheotomies not only reduce resistance and provide improved access to the lower airway but also eliminate the direct connection between the pharynx and trachea established by tracheal intubation.

Principle 6: Prevent panic reactions.

In patients susceptible to dynamic airway collapse, an abrupt need to augment ventilation often precipitates a downward spiral in which the capability of the patient is overwhelmed by the imposed workload. Not only is minute ventilation increased during such episodes, but the resulting augmentation of dynamic hyperinflation impairs muscle strength and endurance. Respiratory acidosis, dyspnea, and anxiety result in an imbalance in the demand/capability relationship that creates a need for aggressive intervention. Anxiolytics, although hazardous to employ, may be extremely helpful in carefully selected circumstances.

Principle 7: Maintain appropriate nutrition, assure adequate hemoglobin concentration, and prevent obstipation.

In stressed and often malnourished patients, the nature and quantity of nutritional support can make the difference between eventual compensation and continued ventilatory insufficiency. Although reasonable caution is advisable, anemia should be reversed and an adequate number of calories should be provided, via the enteral route whenever possible. Care must be taken to ensure that bowel motility is normal; patients with AO frequently develop breathing discomfort because of abdominal distention within a compartment bounded by a hyperinflation-depressed diaphragm.

PRACTICAL MANAGEMENT OF THE VENTILATED PATIENT

INTUBATION

An understandable reluctance to initiate mechanical ventilation in patients with COPD or perennial asthma exists because ventilatory assistance may be needed for prolonged periods and because many such individuals are so chronically disabled as to be miserable or despondent at home—even when everything is going as well as possible from a physiologic viewpoint. The development of comfortable noninvasive systems, coupled with supportive trials and clinical experience, has given rise to the initial use of mask ventilation in those who are alert and can tolerate it. However, the most severely affected patients, especially those with copious, thick, and retained secretions, claustrophobia, anxiety, cardiovascular decompensation, or irreversible somnolence, continue to require intubation to stabilize their deteriorating conditions.²⁹

A mounting load of secretions audibly retained within the central airways generally indicates that the patient is too weak or breathless to expectorate and often portends an imminent crisis. Hence, when this sign arises and cannot be

easily reversed, most physicians consider it to be strong evidence favoring intubation for secretion management and ventilation support. Overt disorganization of the breathing rhythm and gasping or ataxic respirations strongly suggest approaching exhaustion.

INITIAL SUPPORT

POSTINTUBATION PROBLEMS

The first 24-hour period following tracheal intubation and initiation of positive-pressure ventilation may be highly dynamic for the patient with AO. Many of these individuals have depleted intravascular volume and impaired cardiovascular reflexes—features that prepare them poorly to compensate for the suddenly increased pleural pressure and impediment to venous return that usually accompany initiation of mechanical support. In this postintubation phase there is an understandable but unfortunate tendency for the physician to intentionally overventilate the patient, and many patients cough vigorously or fight against the rhythm imposed by the machine.

One reason for the agitation that some patients experience is a sudden buildup of positive intrathoracic pressure through the process of dynamic hyperinflation. When these intubated patients are deeply sedated and paralyzed, respiratory efforts cease and vasodilation occurs related to hypercapnia and sedation. The consequent rise of intrathoracic pressure, coupled with a fall in mean systemic vascular pressure, almost routinely depresses venous return and cardiac output (see Fig. 10.3). Therefore, the physician is well advised to remain alert to the predictable development of cardiovascular depression and hypotension following intubation or sedation and be prepared to intervene to reduce ventilation or to support the circulation at the initially selected level, or both. A catastrophic error is to misinterpret the development of sudden hypotension as the unclinking of tension pneumothorax and then to undertake needle puncture of the chest wall. In such individuals it is also wise to remember the potential contribution of auto-PEEP to hypotension during cardiopulmonary resuscitation attempts.

Shortly after intubation there may be agitation, coughing, and retching related to tube insertion. When this interferes with comfort or ventilation, many lightly sedated patients benefit from 3 to 5 mL of 1% to 2% lidocaine instilled through the endotracheal tube. Instillation may be repeated one or two times, but care should be exercised, as lidocaine is easily absorbed via the lung. Fortunately, intolerance of tube placement gradually abates with sedation and the passage of time.

MACHINE SETTINGS

As a general rule, ventilation should be adequately supported during this initial phase, but it is better to under-ventilate cautiously than to overventilate the patient. One reasonable approach is to use assisted flow-regulated volume-controlled mechanical ventilation, delivered with a square wave profile, with the backup rate set to provide about two thirds of the estimated minute ventilation requirement. Although the flow setting is adjusted empirically to coordinate the cycle lengths of the patient and the ventilator, an initial peak flow setting of approximately four to six

times the minute ventilation requirement (depending on whether the flow profile is square or decelerating, respectively) usually suffices to meet expiratory time requirements and minimize auto-PEEP without imposing undue risks that attend extraordinarily high peak cycling pressures. Assuming a minute ventilation of 12 L per minute, a constant flow setting of about 60 L per minute is usually appropriate. This yields an I:E ratio of approximately 1:4, which is considerably shorter than customary in a patient with normal mechanics who breathes at this level of minute ventilation. Reducing the I:E ratio still further may not improve gas trapping noticeably, as terminal rates of airflow are predictably very low. On the other hand, increasing airflow carries a high pressure and work cost in patients with such severe AO. For similar reasons, a constant inspiratory flow is preferable to a decelerating one when flow-controlled, volume-cycled ventilation is in use. Pressure-targeted ventilation is a sensible choice only if it is monitored closely or adjusted automatically by the ventilator to maintain tidal volume in response to changing airflow impedance.

The triggering threshold of the ventilator is set to be as sensitive as possible, and the auto-PEEP level is estimated when feasible to do so. (Measurement typically requires passive inflation to allow predictable occlusion of the circuit at end-expiration.) If auto-PEEP exceeds 5 cm of water and expiratory flow is limited during tidal breathing (which is almost invariably the case during the initial phase), an uncomfortable patient who makes spontaneous breathing efforts may benefit from the addition of a low level of end-expiratory pressure to counterbalance auto-PEEP and reduce the breathing workload (Fig. 10.9). PEEP levels in excess of 15 cm H₂O may be necessary in some instances to reestablish patency of some air channels.

The plateau pressure is a better guide to the degree of hyperinflation than is the measured level of auto-PEEP, for reasons already given. First, most machines do not allow estimation of auto-PEEP in a patient who is spontaneously triggering the ventilator and varies the length of the respiratory cycle. On the other hand, a plateau pressure estimate is usually recordable during triggered, as well as during controlled, volume-cycled breathing. Just as importantly, the auto-PEEP estimated by central airway occlusion is simply the volume-weighted average of those airways that remain open at end expiration, which generally have shorter time constants and better mechanical properties than those that seal earlier in the expiratory period at higher pressure (see Fig. 10.2).

Figure 10.9 Work of breathing and ventilatory effort are improved in patients with tidal flow limitation by the addition of PEEP (positive end-expiratory pressure) marginally less than the original value of auto-PEEP. Airway pressure (top) and intrapleural pressure (bottom). P_{alv} , alveolar pressure; P_{es} , esophageal pressure.

The flow tracing gives some indication of the underlying presence of gas trapping but does not indicate its severity. For example, a severely obstructed airway may be totally occluded and therefore unable to transmit its high pressure to the pressure sensor located within the machine circuitry. Similarly, a narrow airway may give rise to an almost imperceptible flow at end expiration. Several features of the flow tracing are of value: High-frequency variations of the flow tracing suggest the presence of retained airway secretions or water in the external tubing. An abrupt transition between the earliest part of expiration and what follows (“hockey sticking”) indicates a flow limitation during tidal breathing and the potential value of added PEEP if flow persists to the onset of the next breathing cycle (Fig. 10.10). Several signs appearing in the monitored airway pressure and flow signals have been reported that appear to be signatures of partial central airway occlusion, as by mucus plugging (see Fig. 10.8).²⁸

SUPPORT PHASE MANAGEMENT

After the first hours of ventilatory support, rational management focuses not only on reversal of the underlying problems of infection, bronchospasm, secretion retention, and cardiac insufficiency but also on replenishing spent nutritional reserves and building endurance. It makes sense to support ventilation fully in patients intubated for ventilatory failure while fundamental pathologic processes and

precipitating causes are being addressed—at least for the initial 24 to 48 hours. Because it is not known what intensity of ventilatory effort is best for patients with AO to undertake during the support phase of the illness, controversy exists as to the optimal mode of ventilation. During the support phase, the major ventilation objective as the acute problems causing deterioration are being addressed should be to provide sufficient breathing assistance to alleviate discomfort while not risking deconditioning of the ventilatory muscles. To this end, it is reasonable to use volume- or pressure-targeted assist-control (assisted mechanical ventilation) or synchronized intermittent mandatory ventilation (SIMV). In patients who are not deeply sedated and who breathe chaotically, the latter mode applied with pressure support sufficient to replicate the tidal volume of the mandated breaths may reduce the number of dyssynchronous “collisions” between the rhythms of patient and machine. Adequate sedation must be provided so as to assure comfort and reduce the minute ventilation requirement as other fundamental elements of ventilatory therapeutics are addressed (e.g., antibiotics, corticosteroids, regulation of intravascular volume, secretion expulsion or extraction, cardiovascular support). Assuring adequate oxygenation, ventilatory muscle rest, and restorative sleep deserve emphasis. Deep sedation and muscle relaxants, although occasionally necessary in achieving therapeutic objectives early in the ventilatory process, may prove detrimental when their use is prolonged unnecessarily. Not only does sedation present risks of muscle deconditioning and even neuromyopathy, but secretions tend to pool in dependent areas when breathing efforts and coughs are suppressed. As a general rule, deep sedation and paralysis should not be continued for longer than 40 to 72 hours after intubation.

Apart from improving expiratory resistance and reducing the minute ventilation requirement, another intervention aimed at reducing mean alveolar pressure and auto-PEEP is to modestly lengthen the available expiratory time (e.g., by increasing inspiratory flow rate). The flow rate should initially be set at approximately four times the minute ventilation requirement when using a constant inspiratory flow profile. Extending the expiratory time further is usually fruitless, unless minute ventilation is simultaneously reduced. Decelerating flow profiles are often poorly tolerated by the patient with severe AO who makes spontaneous efforts because the latter half of the inspiratory period may require higher flows than imposed by the tightly regulated and stereotyped flow waveform of the ventilator. Adjustments to the flow criterion off-switch that triggers expiration can help manage this problem during pressure-supported ventilation (Fig. 10.11).

PEEP AND CPAP IN SEVERE AIRFLOW OBSTRUCTION

The deliberate use of PEEP in patients with AO has historically been considered undesirable, but there is now ample reason to believe that most of these patients benefit from the application of low levels of PEEP or continuous positive airway pressure (CPAP).^{5,10,11} When applied downstream of airways that collapse dynamically during the exhalation phase of tidal breathing, PEEP helps to improve the effective triggering responsiveness of the machine without

Figure 10.10 A, Typical flow tracing of a patient demonstrating flow limitation during tidal breathing. B, High-frequency ripple suggests secretions or circuit fluid, whereas “hockey sticking” and linear flow decay during expiration characterize flow limitation.

Figure 10.11 Adjustment of the expiratory flow trigger during pressure support can help to compensate for a slowly decelerating inspiratory flow profile that typifies patients with severe airflow obstruction. The appropriate adjustment in this schematic drawing might be from 25% to 50%.

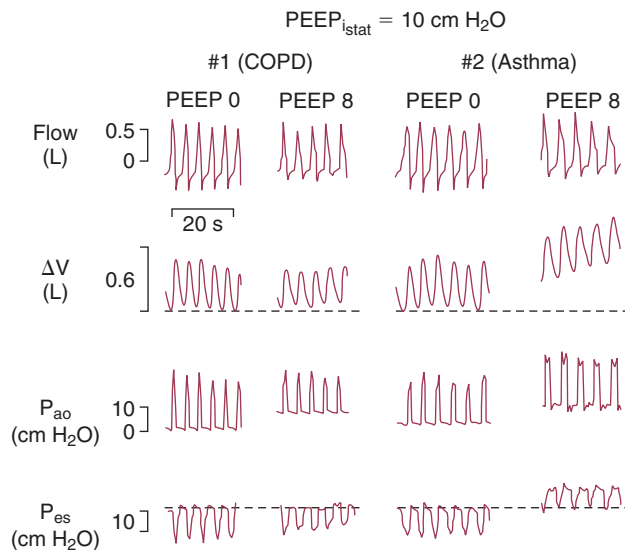

Figure 10.12 Differing responses of a flow-limited patient with chronic obstructive pulmonary disease (COPD) and a non-flow-limited patient with asthma to the application of PEEP (positive end-expiratory pressure). The rises of lung volume (V) and airway opening pressure (P_{ao}) in asthma and the absence of these features in the patient with COPD are demonstrated. (From Ranieri VM, Giuliani R, Cinnella G, et al: Physiologic effects of positive end-expiratory pressure in patients with chronic obstructive pulmonary disease during acute ventilatory failure and controlled mechanical ventilation. *Am Rev Respir Dis* 1993;147:5-13.)

significantly increasing the alveolar pressure or hyperinflation (Fig. 10.12). Most benefit is provided to patients receiving volume-controlled ventilation who do not experience proportionate increases of peak static or peak dynamic cycling pressures after PEEP application.^{10,11,30} When using a fixed level of targeted pressure (pressure control or pressure support), tidal volume may increase after PEEP is applied. This occurs because the added PEEP counterbalances auto-PEEP to allow the applied inspiratory pressure

Figure 10.13 PEEP (positive end-expiratory pressure) evens the flow distribution by counterbalancing auto-PEEP in flow-limited channels with differing levels of gas trapping.

to more effectively drive inspiratory flow. In effect, PEEP improves the pressure gradient that drives *inspiratory* flow and delivers tidal volume. (Should minute ventilation increase with PEEP application, total PEEP may also rise.) Applied PEEP may also help to keep airways more widely patent, and thereby improve secretion clearance. Finally, the application of the external PEEP may help to even the distribution of ventilation among multiple units with heterogeneous time constants (Fig. 10.13).

NEWER MODES OF VENTILATION IN AIRFLOW OBSTRUCTION

Currently, the majority of ventilatory support of AO is still provided with modes of ventilation that are now decades old—flow-controlled, volume-cycled ventilation (“assist-control”); pressure assist control (pressure control, PCV); pressure support (PSV); and SIMV. When combined with PEEP/CPAP and an attentive provider, these time-tested options suffice for the majority of patients. Increasingly, however, practitioners have recognized the need to offload responsibility for minute-by-minute and even intrabreath adjustment of settings for flow and pressure delivery in response to changing conditions of mechanics or ventilatory demand. Patients with dyspnea generally need faster rise of pressure and flows to their target values, unimpeded inspiratory flow, and precise termination of the ventilator’s inspiratory phase so as to avoid collisions between the patient’s and the ventilator’s cycling rhythms. Once set, however, a specified flow pattern regulates the ventilator’s gas delivery, whereas pressure control caps airway pressure at the targeted value. Just as importantly, these time-cycled assist control modes (whether flow or pressure regulated) disregard the duty cycle rhythm variations of the patient’s own drive center; Therefore, asynchrony occurs commonly in these modes, and asynchrony may result not only in dyspnea but also in adverse outcomes.³¹ In either case the *relative* power contribution of the machine declines as effort increases and rises as patient effort declines. Appropriate moment-by-moment intracycle adjustment of flow or pressure is not an option with these “traditional” modes of ventilation. Logic dictates that better synchrony between patient and machine would require continuously monitored feedback and flexibility to adjust to the vagaries of patient need.

Of the newer modes of ventilation, four that have implications for AO have garnered considerable attention and have been incorporated into some of the latest equipment.

AIRWAY PRESSURE RELEASE VENTILATION AND BILEVEL VENTILATION

These modes were neither designed nor intended for patients with lengthy expiratory time constants. Airway pressure release ventilation does not take full advantage of its release phase in patients with lengthy expiratory time constants and therefore ineffectively ventilates unless the release frequency is high. The machine's inspiratory phase pressure is generally higher than that encountered during conventional ventilation, introducing the problems associated with sustained hyperinflation in patients with relatively flexible lungs. Wide variations of auto-PEEP and of release cycle volumes are to be expected. The addition of PEEP may not prove effective in mitigating this variation unless the release phase had been prolonged sufficiently to encounter flow limitation during tidal breathing.

PROPORTIONAL ASSIST VENTILATION

Proportional assist ventilation (PAV), a mode based on the equation of motion of the respiratory system that regulates delivered pressure in proportion to externally sensed inspiratory flow and volume, effectively mimics the actions of an auxiliary muscle in patients without gas trapping.^{32,34} Quite unlike pressure support, which targets the same pressure for every breath, PAV takes resistance and compliance into account and is meant to provide help in proportion to effort (Fig. 10.14). Unfortunately, ventilatory impedance varies considerably in patients with AO, and a considerable fraction of inspiratory muscle effort is spent in counterbalancing variable auto-PEEP, an event that precedes the onset of inspiratory flow. Given the strong dependence of dynamic hyperinflation on minute volume (V_E) and the expiratory time constant, PAV cannot easily fulfill its intended function in patients with severe OA and changing mechanics or minute ventilation needs. Despite these theoretical disadvantages, modern adaptations of PAV—which monitor respiratory mechanics on an ongoing basis—have shown at least equivalent comfort in patient trials, as well as no greater

incidence of missed triggering events and greater tidal volume variability than pressure support, both in invasive and noninvasive settings.³⁵ Although reassuring, no outcome advantage over PSV has yet been convincingly demonstrated in any setting.

NEURALLY ADJUSTED VENTILATORY ASSIST

Neurally adjusted ventilatory assist (NAVA) is similar in concept to PAV in that it attempts to regulate the machine's power support moment by moment by sensing inspiratory effort from the patient.^{34,36} The difference is that the diaphragmatic electromyogram (EMG) provides the signal, so the electrical timing and intensity of phrenic nerve traffic regulate the amplitude of the pressure delivered. NAVA depends on drive to breathe, not the lung's mechanical response. A thin, multielectrode esophageal catheter is used to pick up the strength and contour of the EMG signal, and failure to detect it has not been a major problem. The dynamic hyperinflation drawbacks of PAV in patients with AO are theoretically nullified by placing the "effort detector" closer to the respiratory drive controller—inspiratory efforts related to auto-PEEP are tracked and supported well before inspiratory flow actually begins. Inherent protective reflexes are believed to help the patient avoid overdistention, even if the machine's power boost factor is set inappropriately high. Despite its intuitive appeal, NAVA is still too new to the clinical arena to confirm its theoretical advantage.

ADAPTIVE SUPPORT VENTILATION

Adaptive support ventilation (ASV) is a mode that regulates machine output with pressure-targeted breaths delivered at a variable frequency and with variable pressure in accordance with breathing pattern feedback from the patient (Fig. 10.15). Its intent is to minimize the work of breathing and auto-PEEP, and it does this by optimizing the tidal volume and frequency combination that make up minute ventilation. As such, ASV is one step closer to closed-loop ventilation, in which clinical goals are set, monitored, and accomplished automatically. Once the clinician has determined the PEEP, F_{IO_2} , and cycling triggers for pressure

Figure 10.14 Comparison of pressure support (PSV) and proportional assist (PAV) in response to muscular efforts of varying intensity. The machine pressure mirrors the patient's muscular effort during PAV but not during PSV. (From Younes M: Proportional assist ventilation, a new approach to ventilatory support. *Theory. Am Rev Respir Dis* 1992;145:114-120.)

Figure 10.15 Regulation of ventilation by adaptive support. By changing the number of mandated pressure-controlled breaths and by regulating the pressure support rendered to each triggered cycle, adaptive support aims to keep breathing frequency and tidal volume within acceptable physiologic ranges (see text).

support, he or she must input the patient's ideal body weight (from which the series deadspace is estimated) and the fraction of estimated "normal" minute ventilation the machine should provide. It then varies the mandatory breath number and the pressure targets of a pressure-regulated SIMV algorithm. All the while, the machine tries to nudge the patient toward the ventilatory pattern optimum that *should* minimize deadspace, work of breathing, and auto-PEEP.

In observational studies ASV appears to regulate tidal volume and total breathing frequency effectively, without the need for clinician intervention. As with all advanced modes, however, its performance in severely stressful settings has not been validated and no convincing outcome benefit has yet been reported. As currently implemented, ASV lacks gas exchange feedback, does not calculate total physiologic deadspace, does not account for adjustment to the ideal optimum breathing pattern incurred by disease or deformity, and requires the clinician to specify what percentage of the ideal minute ventilation to shoot for. Nonetheless, it is a promising approach that modifies machine output in response to changing need and may prove to reduce the gas trapping that dysfunctional patterns of AO engender.

WEANING ("LIBERATION") PHASE

Protracted ventilator dependence is perhaps the most feared consequence of intubating patients with exacerbated COPD and perennial asthma. Not only are breathing workloads high, but the ability of the patient to sustain them is compromised by muscle weakness, hyperinflation, disadvantageous thoracic geometry, blunted ventilatory drive, and abnormal cardiovascular function. Rational management of the weaning patient with AO includes provision of adequate rest and nutritional support, enhancement of neuromuscular and cardiovascular function, and minimization of the breathing workload. Maintenance of positive mental attitude can greatly speed the weaning process.

Patients may fail to wean from mechanical ventilation for a wide variety of reasons. Among these are hypoxemia, cardiac arrhythmias, cardiovascular instability, and psychological dependence. However, imbalance between ventilatory capability and demand is perhaps the most common reason for failure to wean in patients with ventilatory failure either of itself or because it provokes one or more of the other factors just mentioned.^{37,38}

PREDICTING READINESS FOR SPONTANEOUS BREATHING

In clinical practice a panel of indices has long been used to predict the outcome of the weaning trial. Most individual elements of these demand or capability panels can be classified as indicators of either one or the other, but not both. Some capability indicators depend on patient effort as well. Thus, a maximal inspiratory pressure measurement exceeding 30 cm H₂O and a minute ventilation requirement of less than 10 L per minute are standard components of the traditional predictive battery. Although minute ventilation has been criticized as unreliable when used alone, it is still a highly useful observation, particularly when referenced to blood gas measurements and integrated into an evaluation

of other panel elements. When the patient is calm, a high degree of variation of minute ventilation suggests some degree of ventilatory reserve.³⁹ Because the product of minute ventilation and the average inspiratory pressure per breath are the main components of the breathing workload, minute ventilation must not be disregarded, even when more integrative indices are in use, such as the frequency-to-tidal volume ratio (rapid shallow breathing index, RSBI).⁴⁰ For example, a rising RSBI does not necessarily portend failure if minute ventilation rises as well. Published criteria for RSBI lose reliability in the presence of neuromuscular weakness, severe restriction, or chronic illness requiring ventilator support.³⁸

Numerous other weaning outcome indices have been suggested over the years, but none stands alone as infallible, including the RSBI. The most successful of these indicators reliably relate power requirement to the ability of the patient to sustain it. Certain physiologic measurements such as the $P_{0.1}$ (a measurable indicator of ventilatory drive now offered on some of the newest ventilators) have predictive appeal. These are not universally available, however, and cannot be relied on for definitive judgment in every case. Because many factors may limit the patient's ability to be removed from the ventilator, more than one single indicator is usually necessary to observe. Alertness, degree of cardiovascular compensation, clinical trajectory over the preceding days, oxygenation status, secretion load, upper airway patency, coughing efficiency, and psychological well-being are as important as any single predictive measure based on mechanics and muscle strength. Successful weaning protocols take all such factors into account.^{37,38,40}

Repeated failure to wean is often explained by cardiovascular factors such as ischemia and diastolic dysfunction. This is especially true when parameters based on ventilation appear favorable. Clues may appear in the form of cardiac dysrhythmias and an unfavorable excess of fluid intake over output. In part for such reasons, weaning protocols must be constructed carefully; failure to meet weaning criteria must be considered a cue to undertake a careful review of all potential factors that prevent success, not necessarily an indication to allow a bit more time with unchanging therapy.

WEANING APPROACHES

PREPARATIONS

Preparations for ventilator withdrawal should include ensuring adequate nocturnal rest with fully supported breathing, adequate nutrition, good circulatory reserve, avoidance of excessive intravascular volume and edema, treatment of infection, appropriate body positioning, and judicious sedation.^{37,40} Obstipation, urinary retention, pleural effusions, gastric distention, musculoskeletal pain, severe anemia, and chemical imbalances must be avoided or reversed. During the full support phase of ventilation, care must be taken not to allow sedatives to accumulate or secretions to collect within the airways. Heat-moisture exchangers do not hydrate the airway secretions reliably, especially in low humidity environments or when high inspired concentrations of oxygen have been in use. Active humidification often proves the better choice when secretion load or clearance is problematic. Inspection of the central airway prior to attempted extubation may be rational when the patient has been

ventilated for lengthy periods, as inspissated secretions may not have been adequately suctioned. Withdrawal of sedatives should be attempted on a daily basis in an effort to prevent oversedation, especially when the sedating drug is infused continuously. The patient must not depend on high levels of PEEP for either oxygenation or ventilatory comfort. It must be remembered that PEEP and CPAP aid ventilation in patients with flow limitation and auto-PEEP.

The use of frequent wakeups, intermittent dosing, and short-acting sedatives (especially in the hours prior to spontaneous breathing trials and weaning attempts) has helped to avoid the common problem of benzodiazepine metabolite hangover. When benzodiazepines are given for lengthy periods, lingering sedative effects may persist for up to a week after the last dose is given. Dexmedetomidine (Precedex), a sedative agent with relatively little hypnotic action, has proved helpful in some cases in which calm alertness is desired but difficult to otherwise achieve.⁴¹ In well-selected cases, alertness-enhancing drugs such as modafinil (Provigil) have been helpful. Delirium that interferes with weaning occurs commonly and may benefit from such agents as quetiapine and olanzapine.⁴²

SPECIFIC MODES

Considerable effort has gone into the delineation of the optimal weaning technique. It is generally true that the majority of patients do not need a lengthy period of gradual machine withdrawal once the primary problems that brought the patient to medical attention have been treated and the adverse effects of fluids and drugs given during their acute problems have been addressed.⁴³ It is also true, however, that a distinct subset of these patients with underlying AO or other chronic impairments not amenable to therapy cannot tolerate abrupt transitions to spontaneous breathing. More graded reloading is sometimes necessary because of fragile cardiovascular status, neuromuscular weakness, or psychological factors. Pressure support ventilation is generally to be preferred to SIMV, as the muscle and cardiovascular reloading process tends to be less sudden and more predictable. Intermittent T-piece weaning makes little sense to employ in these patients; each transition to fully spontaneous breathing abruptly imposes a full stress workload. All patients, however, should be *tested* with low-level pressure support or T-piece breathing before any gradual withdrawal of support is undertaken, as the latter may not be necessary.⁴⁴ Once the patient is breathing on low-level pressure support or from an oxygenated T-piece, observation should be continued at least 30 minutes, but generally less than 2 hours before decannulation of the airway is attempted. During the attempt at spontaneous breathing, the patient must be watched carefully and not allowed to fatigue because recovery from that condition may require more than a day to restore energy reserve.⁴⁵

PERIEXTUBATION PHASE

In intubated patients suspected of upper airway obstruction, a cuff deflation test should be conducted before decannulating the airway. This is performed by elevating PEEP to 10 to 20 cm H₂O immediately in advance of deflation. An audible leak should be heard if the glottic space is not prohibitively tight. The sitting position, manipulation of head

position and a temporary increase of PEEP may help break a “mucus seal” that otherwise prevents gas leakage. In questionable cases, advance preparations should be made for urgent intervention, should that prove necessary after tube extraction.

The immediate postextubation phase should be as carefully managed as the ventilated one. The first 24 hours off the ventilator are often difficult and tenuous, but in successful cases there should be progressive improvement. Coughing, deep breathing, adequate oxygenation, avoidance of arrhythmias, adequate bronchodilation and airstream hydration, maintenance of a clear central airway, and a mechanically efficient posture are crucial. Oral refeeding must be undertaken with extreme caution because swallowing difficulty in chronic dysfunction can persist days to weeks after extubation in patients who have been ventilated for lengthy periods. CPAP and intermittent noninvasive ventilation may be especially helpful in selected patients,⁴⁶ especially in the nighttime hours. Noninvasive ventilation maintains patency of an edematous upper airway and provides ventilation support during sleep. This is often important in patients who have received sedating medications or are sleep deprived. It must be used judiciously, however, and carefully applied. Ventilation by pressurized mask impedes secretion clearance, and if a humidifier is not used, mouth breathing during bilevel positive airway pressure (BiPAP) dries secretions and encourages displacement of oral material into the central airway. Therefore, it is common for patients who receive mask ventilation after extubation to require reintubation for clearance of thickened airway mucus.

KEY POINTS

- By assuming a major portion of the ventilator workload, mechanical ventilation affords the opportunity to rest the respiratory muscles while maintaining pH homeostasis and oxygenation, thereby averting progressive ventilatory failure or respiratory arrest, or both.
- Increased resistance to airflow and gas trapping is responsible (directly or indirectly) for many of the physiologic disturbances that typify AO.
- When dynamic collapse occurs during tidal respiration, and breathing requirements are high, there is little alternative to hyperinflation, CO₂ retention, or both.
- Ventilation-perfusion mismatching is widespread in patients with severe AO, reducing the efficiency of carbon dioxide elimination.
- Pressure-targeted modes of ventilation, exemplified by pressure control and pressure support, have become increasingly popular in the care of intubated patients, as well as those receiving noninvasive ventilation by facemask.
- Most patients hospitalized with exacerbations of asthma or COPD can be managed effectively by

Continued on following page

KEY POINTS (Continued)

- regimens that incorporate aggressive secretion clearance techniques, antibiotics, corticosteroids, intensified bronchodilators, hydration, cardiovascular support, and supplemental oxygen.
- The first 24-hour period following tracheal intubation and initiation of positive-pressure ventilation is a highly dynamic one for the patient with AO.
 - In the majority of cases, ventilatory support of AO is still currently provided with modes of ventilation that are now decades old—flow-controlled, volume-cycled ventilation (“assist-control”); PCV; PSV; and SIMV.
 - Careful attention to the nature and quantity of sedation, coupled with daily attempts to awaken and test spontaneous breathing, accelerates liberation from mechanical ventilation.
 - The postextubation phase should be as carefully managed as the ventilated one. The first 24 hours off the ventilator are often difficult and tenuous. During this phase, close attention to secretion clearance, sleep, upper airway patency, and fluid management will help to avert reintubation.

Extracorporeal Support

Since the first description of acute respiratory distress syndrome (ARDS) in 1967,¹ mechanical ventilation has been the primary “buying time” treatment for acute lung injury (ALI). Mechanical ventilation is not a “gas exchanger,” but instead replaces, totally or partially, the force normally generated by the respiratory muscles to promote ventilation, providing muscle rest. The effects of mechanical ventilation on gas exchange are indirect and include (1) better clearance of carbon dioxide (CO₂) by the power of the mechanical ventilator to expand the diseased and collapsed lung; (2) improvement in oxygenation by preventing alveolar hypoxia caused by hypoventilation; (3) improvement in oxygenation by increasing inspiratory oxygen fraction, which affects alveolar partial pressure of oxygen (PAO₂); (4) improvement in oxygenation by opening lung regions otherwise collapsed (alveolar recruitment); and (5) improving oxygenation by maintaining positive end-expiratory pressure (PEEP), preventing the collapse of the lung regions previously recruited during the inspiratory phase.

The negative effects of mechanical ventilation are interwoven with its positive effects. First, the driving force applied by the ventilator, if excessive, may alter, in different ways, the lung parenchyma and produce ventilator-induced lung injury (VILI). Second, the positive-pressure ventilation

unavoidably turns the physiologically negative intrathoracic pressures into positive pressures. In consideration of this, the guiding principle of mechanical ventilation of ARDS patients should be that, whenever one manipulates the ventilator settings, one should refer to one polar star: The new setting is less harmful to the lung structure than the previous one.

HISTORY

Extensive reviews on the history of mechanical ventilation of ARDS can be found elsewhere.^{2,3} In the 1970s, mechanical ventilation was recommended and performed with low PEEP and high tidal volume: “. . . larger tidal volumes (10 to 15 per kilogram) are preferable, having been used in several thousand ventilated patients with no evidence of development of pulmonary damage.”⁴ Today, this advice seems inconceivable. At that time, the main concerns were the putative harm of high inspiratory oxygen fraction and the hemodynamic impairment. It was later recognized in experimental and clinical settings⁵⁻⁷ that high-volume/high-pressure mechanical ventilation could severely damage the lung parenchyma. Such lesions, primarily attributed to the

excessive airway pressure, were collectively classified as *barotrauma*. In the same period, Suter and colleagues⁸ published a report that, for the first time, systematically described the interaction between PEEP, lung mechanics, gas exchange, and hemodynamics.

In the 1980s, based on the work of Dreyfuss,^{9,10} the focus progressively shifted from the potential harm of pressure to the harm of volume (overdistention), a concept that was popularized as *volutrauma*.¹¹ In the mid-1980s, the application of computed tomography (CT)^{12,13} and the quantitative approach to CT analysis¹⁴ led to the concept of *baby lung*,^{15,16} which accounted for most of the previous observations on respiratory mechanics, gas exchange functionality, and potential harm of mechanical ventilation. The premise of this line of thought is that high pressure or excessive distention applied to a small fraction of the lung parenchyma (with a size similar to the lung of a baby) unavoidably leads to structural lesions of the lung regions open to ventilation. Total *lung rest* was achievable with the use of extracorporeal CO₂ removal, targeted to prevent the damages of high-pressure/high-volume ventilation.¹⁷⁻¹⁹ The target of mechanical ventilation shifted toward lung protection, rather than normal gas exchange functionality. Hickling and associates²⁰ proposed the “permissive hypercapnia” strategy for ARDS, providing “gentle treatment” of the portion of the lung that remains open to ventilation (the baby lung) through less aggressive mechanical ventilation, at the acceptable price of an abnormally higher arterial partial pressure of carbon dioxide (PaCO₂).

A large amount of experimental and clinical data over the years has supported the approach of a *lung protective strategy*.²¹⁻²⁵ Low tidal volume prevents the excessive global stress and strain of the baby lung, whereas higher PEEP prevents the regional excessive stress and strain by avoiding alveolar collapse and reopening during mechanical ventilation.²⁶ These mechanical events are associated with an inflammatory reaction of the epithelial and endothelial lung cells (*biotrauma/atelectrauma*) as shown by the seminal study of Tremblay and colleagues²⁷ (see also work of Dreyfuss and Saumon¹¹ and Tremblay and Slutsky²⁸). The literature to date supports the thought that the harm of mechanical ventilation is due to excessive global or regional stress and strain.²⁹ This situation leads to two results—a physical rupture of the lung and a mechanically induced inflammation of the lung parenchyma, constituting VILI. The best “mechanical ventilation” would provide adequate gas exchange with the lowest amount of VILI.

PHYSIOLOGIC BASIS OF MECHANICAL VENTILATION

DRIVING FORCE

To ventilate the respiratory system, force is required. The driving force for ventilation under normal circumstances is provided by the respiratory muscles. During spontaneous breathing, the thoracic cage expands. This causes a decrease in intrathoracic pressure (pleural pressure, Ppl) relative to the atmosphere (in normal conditions approximately 2 mm Hg of ΔPpl is sufficient to expand the thoracic cage

by 0.5 L). Because the lungs are connected in series with the thoracic cage, their volume is expanded to a near equal extent (not considering the blood shift³⁰). The force that distends the lung is the pressure difference between the alveoli and the pleural cavity (the transpulmonary pressure, PL). As the lung expands, the alveolar pressure becomes subatmospheric, and gas flow is generated (*inspiration*). When the respiratory muscles relax, the potential energy accumulated in the respiratory system (lung and chest wall) returns the chest wall and the lung parenchyma to the resting position (*expiration*). In spontaneously breathing subjects, the driving force (muscular pressure, ΔP_{musc}) is spent partly to expand the chest wall (ΔP_{pl}), partly to expand the lung (ΔP_L), and partly to overcome the resistances to the gas flow. In *quasi-static* conditions, in which the resistances to gas flow are negligible:

$$\Delta P_{\text{musc}} = \Delta P_{\text{pl}} + \Delta P_{\text{L}}$$

During positive-pressure mechanical ventilation, the rules are exactly the same, with the exception that ΔP_{musc} is substituted by the force provided by the ventilator, and the force is applied to the lung parenchyma and not to the chest wall. The driving pressure, which coincides with the airway pressure at plateau during an end-inspiratory pause (in quasi-static conditions), is spent first to expand the lung and second to expand the chest wall:

$$\Delta P_{\text{aw}} = \Delta P_{\text{L}} + \Delta P_{\text{pl}}$$

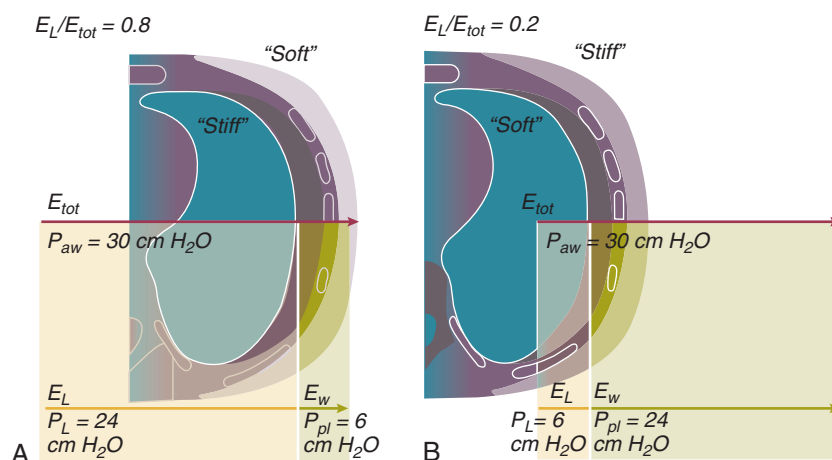

In spontaneous breathing and during positive-pressure mechanical ventilation, the distending force of the lung is the transpulmonary pressure. During spontaneous breathing, pleural pressure is negative (facilitating venous return), whereas during mechanical ventilation it is positive (impairing venous return). What matters from the pulmonary perspective is the distending force (i.e., the transpulmonary pressure [ΔP_L]), whereas what matters from the hemodynamic perspective is the pleural pressure (ΔP_{pl}).

TRANSPULMONARY PRESSURE

At the same driving force applied to the whole respiratory system (lung and chest wall), the resulting transpulmonary pressure, ΔP_L, may be extremely variable. If the lung is relatively “stiff,” and the chest wall is relatively “soft” (e.g., during pulmonary fibrosis or ARDS of pulmonary origin), a greater fraction of the driving pressure is spent to distend the lung (high transpulmonary pressure). In contrast, if the lung is relatively soft, but the chest wall is relatively stiff (e.g., in the presence of an abdominal disease or severe obesity), most of the driving force is spent to move the chest wall (high pleural pressure).

To express this phenomenon quantitatively, it is convenient to consider the concept of *elastance*. The elastance of the whole respiratory system is the driving force (ΔP_{aw}) required to increase the lung and the chest wall 1 L above their resting position (E_{tot} = ΔP_{aw}/1 L). Part of this driving force is spent to increase the lung volume of 1 L (E_L = ΔP_L/1 L), and part is spent to increase the chest wall by the same amount (E_{cw} = ΔP_{pl}/1 L). Transpulmonary pressure (ΔP_L) can be expressed as the driving force times the ratio between lung elastance and total elastance of the respiratory system:

Figure 11.1 Two examples of E_L/E_{tot} variability in patients with acute lung injury/acute respiratory distress syndrome. **A**, $E_L/E_{tot} = 0.2$. **B**, $E_L/E_{tot} = 0.8$. This variability implies that for the same airway pressure applied (e.g., 30 cm H₂O), the resulting transpulmonary pressure (PL) may range from 6 to 24 cm H₂O.

$$\Delta P_L = \Delta P_{aw} \times E_L/E_{tot}$$

The transpulmonary pressure for a given driving pressure uniquely depends on the ratio of lung elastance to respiratory system elastance. In normal subjects E_L/E_{tot} is approximately 0.5, whereas in patients with ARDS it may range from 0.2 (e.g., in obese patients or in patients with high intra-abdominal pressure) to 0.8 (e.g., in patients with a very small baby lung and a normal chest wall elastance). This variability implies that for the same driving force applied and read on the ventilator display (e.g., 30 cm H₂O), the resulting transpulmonary pressure may range from 6 to 24 cm H₂O (Fig. 11.1).

FORCE-BEARING STRUCTURE OF LUNG PARENCHYMA

The transpulmonary pressure is applied to the force-bearing structure of lung parenchyma, the extracellular matrix, which constitutes the *lung skeleton*.³¹ The lung skeleton is a complex and metabolically active structure that includes a network of several components—elastin, collagen, and proteoglycans. All these molecules are involved in determining the mechanical characteristics of the respiratory system. The elastin may be considered as an elastic spring, whereas the unextensible collagen, which is folded at end expiration and completely unfolded at a lung volume equal to total lung capacity, acts as a stop-length fiber.^{32,33} The proteoglycans stabilize the collagen-elastin network, contributing to lung elasticity and alveolar stability at low and medium lung volumes.³⁴

The matrix of elastin, collagen, and proteoglycans is arranged in two main fiber systems: (1) the *axial* system, which originates from the pulmonary hilum and runs deeply into the lung parenchyma down to the alveolar level, where it joins (2) the *peripheral* system, which originates from the visceral pleura and runs centripetally within the lung parenchyma.³¹ The lung skeleton may be considered as a continuous elastic structure that reaches its extension limits at total lung capacity, a lung volume equal to about threefold the lung resting volume. At this level of alveolar distention, the collagen is completely unfolded, and further expansion is prevented. The epithelial and endothelial cells do not directly bear the applied forces because they are anchored

to the extracellular matrix by a series of structural proteins (integrins), which are connected to the cytoskeleton. During lung expansion, the epithelial and the endothelial cells modify their shape.

It is well documented that mechanically induced cellular deformation activates a series of mechanosensors with the production of several inflammatory mediators, such as cytokines (interleukin 6, tumor necrosis factor- α , and interferon- γ),^{27,35} metalloproteinases (enzymes involved in the remodeling of the matrix),³⁶ leukotrienes,³⁷ and interleukin 8,³⁸⁻⁴⁰ the most powerful attractor of neutrophils.⁴¹ Gross barotrauma (e.g., pneumothorax) is due to the stress at rupture of the lung skeleton, whereas intrapulmonary inflammation is primarily due to the excessive strain of the epithelial and endothelial cells.

CONCEPT OF STRESS AND STRAIN

Stress is the applied force, and strain is the linear deformation of material. In the whole lung, the rough approximation of stress is the transpulmonary pressure, whereas the approximation of the average strain is the change in volume relative to the lung resting volume. The ratio between alveolar stress and strain is defined as *lung-specific elastance* (E_{spec}), which is mathematically defined as:

$$\Delta P_L = E_{spec} \times \Delta V/V_0$$

where ΔV is the volume variation applied to the lung (i.e., the tidal volume), and V_0 is the lung resting volume (i.e., the functional residual capacity at atmospheric pressure [without any application of PEEP]). The lung-specific elastance is the transpulmonary pressure required to double the lung resting volume (i.e., the ΔP_L when $\Delta V/V_0$ is equal to 1). In ARDS, lung-specific elastance is similar to normal,^{16,42} reinforcing the concept of the baby lung (lung is small and not stiff), and questions the use of normalizing the tidal volume to the ideal body weight. The same tidal volume per kilogram may result in completely different strain according to the size of the baby lung (the V_0 of the previous equation). For example, a 70-kg man with ARDS may have, according to the severity of the lung injury, a residual baby lung equal to 60%, 40%, or 20% of his normal lung size. If the ventilator is set to deliver 10 mL/kg, the actual delivered tidal volume would generate an alveolar strain, which would

result from the application, in normal lung, of a tidal volume equal to 17 mL/kg, 25 mL/kg, and 50 mL/kg, values associated with a significant lung injury in laboratory studies.^{11,29}

Recently we attempted to quantify the relationship between stress-strain and VILI in healthy animals. We found that edema formation was a threshold phenomenon, induced by mechanical ventilation when the global strain reaches a critical value of about 2.⁴³ This threshold roughly corresponds to the point where the stress-strain curve loses its linearity and starts an exponential growth, indicating that some lung regions reach their own total capacity and cannot expand any further. At this level of strain, in a period of 24 to 48 hours the mechanical ventilation is lethal and the increased lung weight (two to three times the baseline) is associated with a striking impairment of respiratory mechanics, gas exchange, hemodynamics, inflammation, distal organs damage, and 100% mortality rate. This lethal strain, and associated stress, however, is rarely applied in clinical practice. To explain VILI in a diseased lung, therefore, alternative phenomena must be taken into account as the lung dishomogeneity and the presence of stress rise, which will be discussed later.

PATIENT CHARACTERIZATION

Using the least harmful mechanical ventilation setting requires a preliminary knowledge of the main pathophysiologic characteristics of the patient. The most relevant characteristics are the kind and amount of the lung injury, the chest wall elastance, and the lung recruitability.

GAS EXCHANGE

OXYGEN

PaO_2 , PaO_2 -to-fraction of inspired oxygen ratio ($\text{PaO}_2/\text{FiO}_2$), and Riley's shunt fraction⁴⁴ are the most commonly used variables to assess the severity of lung injury. In particular, the $\text{PaO}_2/\text{FiO}_2$ thresholds of 300 and 200 were used to define ALI (300) and ARDS (200) according to the American-European Consensus Conference on ARDS.⁴⁵ Consequently, the $\text{PaO}_2/\text{FiO}_2$ ratio is perceived as a key variable by most intensive care unit (ICU) physicians: The lower the $\text{PaO}_2/\text{FiO}_2$ ratio, the greater the lung injury. This equivalence is highly questionable. First, in most large studies on ARDS, no association was found between hypoxemia and outcome.⁴⁶ In the large study showing a better outcome with low tidal volume compared with higher tidal volume, the $\text{PaO}_2/\text{FiO}_2$ ratio was significantly lower in the low tidal volume group despite ending with better outcome.²⁵ Finally, the $\text{PaO}_2/\text{FiO}_2$ ratio was not different in patients with early, intermediate, and late ARDS, suggesting that oxygenation was not dependent on the structural changes of lung parenchyma occurring with time.⁴⁷ In a study⁴⁸ in which the lung severity was assessed by CT scan (and defined as a fraction of the gasless tissue), we did not find significant changes of $\text{PaO}_2/\text{FiO}_2$ ratio over a wide range of nonaerated tissue (Fig. 11.2), and $\text{PaO}_2/\text{FiO}_2$ ratio was not associated with outcome.

Most data suggest that $\text{PaO}_2/\text{FiO}_2$ ratio is a weak indicator of the overall lung severity, with compensatory rearrangement of perfusion during ARDS limiting the deterioration of oxygenation. The same limits apply when $\text{PaO}_2/\text{FiO}_2$ ratio

Figure 11.2 Frequency distribution of nonaerated lung tissue, expressed as a proportion of the total lung weight, recorded at 5 cm H_2O positive end-expiratory pressure in 68 patients with acute lung injury/acute respiratory distress syndrome (ALI/ARDS). Green columns represent patients with $\text{PaO}_2/\text{FiO}_2$ less than 300 (ALI without ARDS), whereas purple columns represent patients with $\text{PaO}_2/\text{FiO}_2$ less than 200 (ARDS). The nonaerated lung tissue was defined as the lung tissue having a physical density at computed tomography scan image analysis between +100 Hounsfield units (HU) and -100 HU, representing the portion of lung parenchyma that is consolidated or collapsed or both (i.e., the lung injury severity). (With permission from Gattinoni L, Caironi P, Cressoni M, et al: Lung recruitment in patients with the acute respiratory distress syndrome. *N Engl J Med* 2006;354:1775-1786.)

changes are used to assess lung recruitment. Because this maneuver is unavoidably associated with changes of perfusion (global or regional), the increase of $\text{PaO}_2/\text{FiO}_2$ ratio may be partly due to decrease of perfusion, as shown in the 1980s.⁴⁹⁻⁵¹ Most data suggest that the use of oxygenation variables alone to assess lung severity is misleading.

CARBON DIOXIDE

Although less considered, the variables derived from CO_2 , as the total or alveolar deadspace, seem to be of greater value in assessing lung severity. It has been shown in ALI/ARDS patients that deadspace at entry is a strong predictor of outcome,⁵² and that Paco_2 for the same total ventilation steadily increases from early to intermediate and to late ARDS, reflecting the lung structural changes.⁴⁷ The Pco_2 response to prone position (in contrast to Po_2 response) is a strong prognostic index of mortality.⁵³ Most data suggest that CO_2 -related variables (deadspace), more than $\text{PaO}_2/\text{FiO}_2$ ratio, reflect the severity of lung injury (and associated mortality rate) at the time of presentation and the structural changes of lung parenchyma occurring with time (fibrosis, *Pneumocystis*, and possibly perfusion defects).

RESPIRATORY MECHANICS, CHEST WALL ELASTANCE, AND LUNG VOLUME

In the original description of ARDS,¹ the low compliance (i.e., high elastance) of the respiratory system was a landmark of the syndrome. The respiratory system compliance is not considered in the current definition of ARDS,

however.⁴⁵ For years, the low compliance was attributed uniquely to the lung component (lung stiffness and lack of surfactant). Quantitative CT shows, however, that the respiratory system compliance primarily reflects the size of lung open to gases (the baby lung^{14,16}), suggesting that the intrinsic functioning lung elasticity in ARDS is close to normal (the lung is “small” rather than “stiff”). More than gas exchange, the respiratory system compliance indirectly assesses the lung injury severity (the smaller baby lung, the greater lung injury),⁵⁴ as confirmed in animal experiments.⁵⁵ Another variable also must be taken into account—the elastance of the chest wall. It has been shown in a significant portion of ALI/ARDS patients that the chest wall elastance is greater than normal because of increased intra-abdominal pressure, obesity, or severe edema.⁵⁶ In patients with extrapulmonary ARDS⁵⁷ and in obese patients,⁵⁸ the high elastance of the respiratory system may be due to the chest wall and to the lung derangement. Measurement of intra-abdominal pressure should be considered when selecting mechanical ventilator settings.

SEVERITY OF LUNG INJURY AND LUNG RECRUITABILITY

CT can be used to assess the severity of lung injury by measuring the fraction of nonaerated lung tissue at end expiration (end expiration pause at 5 cm H₂O). This fraction includes the lung tissue that is “consolidated” (i.e., not openable at 45 cm H₂O airway pressure) and the tissue that is collapsed but openable at 45 cm H₂O. These values were chosen to produce a minimal risk during the maneuver and because this is the most frequently used in the literature for recruitment maneuver.⁵⁹ In patients with elevated chest wall elastance, the resulting transpulmonary pressure could be insufficient, however, to overcome the opening pressure of some pulmonary units.

The total fractions of nonaerated lung tissue (consolidated plus recruitable) and the recruitable tissue alone (tissue that regains aeration at 45 cm H₂O airway pressure) are strongly associated with mortality rate. The data of Figure 11.2 show the inadequacy of the term ALI/ARDS, as currently defined, to describe the lung injury.⁴⁸ The data refer to a population of ALI/ARDS patients, classified according to the American-European Consensus Conference on ARDS,⁴⁵ in which a CT-based quantitative analysis of the whole lung parenchyma at 5 cm H₂O PEEP was performed. As shown in Figure 11.3, the fraction of the nonaerated lung tissue (consolidated or collapsed or both) may range from 5% to 70% of the entire lung parenchyma. Patients meeting ALI/ARDS criteria may have a baby lung size very close to that of normal subjects, or a baby lung that is just a small fraction of the expected normal lung. When the distending force is applied to the lungs by the mechanical ventilator, previously collapsed lung regions may open. Lung recruitability may be expressed as the amount of lung tissue regaining aeration when increasing the applied driving force from 5 to 45 cm H₂O. As shown in Figure 11.3, in some patients, lung recruitability was almost negligible, whereas in others it was equal to 25% to 35% of the entire lung parenchyma. Lung recruitability was strongly associated with the fraction of nonaerated tissue, suggesting that the greater the inflammatory edema, the greater the lung

Figure 11.3 Frequency distribution of 68 patients with acute lung injury/acute respiratory distress syndrome (ALI/ARDS) according to the percentage of potentially recruitable lung, expressed as the percentage of total lung weight. ALI without ARDS was defined by a $\text{PaO}_2/\text{FiO}_2$ ratio less than 300, but not less than 200; ARDS was defined by a $\text{PaO}_2/\text{FiO}_2$ ratio less than 200. The percentage of potentially recruitable lung was defined as the proportion of lung tissue in which aeration was restored at airway pressures between 5 and 45 cm H₂O. (With permission from Gattinoni L, Caironi P, Cressoni M, et al: Lung recruitment in patients with the acute respiratory distress syndrome. *N Engl J Med* 2006;354:1775-1786.)

collapse. It seems that the best way to assess the overall lung severity and the related lung recruitability, both strongly associated with mortality rate, is the CT scan analysis. Physiologic variables are poor indicators of the severity of the lung injury. This relationship is shown in Figure 11.4—for a large variation of lung injury, ranging from 20% to 60% of the lung parenchyma, the values of $\text{PaO}_2/\text{FiO}_2$ ratio, lung compliance, and Paco_2 greatly overlap.

ARDS CLASSIFICATION

Although, in our opinion, the definition of ARDS should include a quantitative estimate of the lung edema, because this is not feasible in most of the ICU, alternative ways for defining ARDS have been sought. ARDS was first defined by Ashbaugh and coworkers in 1967.¹ Several other definitions have been introduced afterward, up to the American-European Consensus Conference (AECC) in 1994.⁴⁵ This conference defined ARDS as the acute onset of hypoxemia ($\text{PaO}_2/\text{FiO}_2 \leq 200$) with bilateral infiltrates seen at x-ray study and no evidence of left atrial hypertension, and these parameters were largely used for the enrollment of patients in clinical trials. In 2011, a panel of experts, under the initiative of the European Society of Intensive Care Medicine endorsed from the American Thoracic Society and Society of Critical Care Medicine, convened to develop what has been called the “Berlin definition.”⁶⁰ The final Berlin definition is reported in Table 11.1. Stages of mild, moderate, and severe ARDS were related to increased mortality rates and increased median duration of mechanical ventilation in survivors.

Figure 11.4 Mean \pm standard deviation values of respiratory variables of a population of 68 patients with acute lung injury/acute respiratory distress syndrome. Blue columns represent $\text{PaO}_2/\text{FiO}_2$ ratio at positive end-expiratory pressure (PEEP) 5 cm H_2O (mm Hg), red columns represent respiratory system compliance at PEEP 5 cm H_2O (mL/cm H_2O), green columns represent deadspace fraction (%), and gold columns represent alveolar deadspace fraction (%). * $P < 0.05$ versus patients with a fraction of nonaerated tissue recorded at 5 cm H_2O PEEP less than 0.2. † $P < 0.05$ versus patients with a fraction of nonaerated tissue recorded at 5 cm H_2O PEEP ranging from 0.2 to 0.4. The continuous purple line represents the likelihood of death predicted by the fraction of nonaerated lung tissue recorded at 5 cm H_2O PEEP ($P = 0.015$). Weight is a poor surrogate of strain because ARDS patients with similar body weights may have completely different lung sizes and consequently different levels of strain at equal tidal volumes. This is confirmed by the plateau pressures measured in these different studies (see Fig. 11.5). As shown for the same tidal volume per ideal body weight, the plateau pressures are widely distributed with huge overlap between the studies. This reflects a wide distribution of the respiratory system compliance and consequently of the lung size.

MECHANICAL VENTILATION IN ACUTE RESPIRATORY DISTRESS SYNDROME: AVAILABLE EVIDENCE

SETTING TIDAL VOLUME

The main results of several outcome studies specifically designed to compare different tidal volumes are summarized in Table 11.2. A survival benefit was found in the study comparing 6 mL/kg tidal volume versus 12 mL/kg, the highest tidal volume range tested,²⁵ whereas no survival differences were found in the other studies, which compared intermediate values of tidal volumes.^{21,23,24} As previously discussed, the tidal volume per ideal body weight is a poor surrogate of strain because ARDS patients with similar body weight may have completely different lung sizes and consequently different strain at equal tidal volume. This is confirmed by the plateau pressures measured in these different studies (Fig. 11.5). As shown for the same tidal volume per ideal body weight, the plateau pressures are widely distributed with huge overlap between the studies. This reflects a wide distribution of the respiratory system compliance and consequently of the lung size.

Table 11.1 The Berlin Definition of ARDS

Defining Features	Criteria
Timing	Within 1 week of a known clinical insult or new/worsening respiratory symptoms
Chest imaging*	Bilateral opacities, not fully explained by effusions, lobar/lung collapse, or nodules
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload Need for objective assessment (e.g., echocardiography) to exclude hydrostatic edema if no risk factor is present
Oxygenation†	
Mild	$200 < \text{PaO}_2/\text{FiO}_2 \leq 300$ with PEEP or CPAP ≥ 5 cm H_2O †
Moderate	$100 < \text{PaO}_2/\text{FiO}_2 \leq 200$ with PEEP ≥ 5 cm H_2O
Severe	$\text{PaO}_2/\text{FiO}_2 \leq 100$ with PEEP ≥ 5 cm H_2O

ARDS, acute respiratory distress syndrome; PaO_2 , partial pressure of arterial oxygen; FiO_2 , fraction of inspired oxygen; PEEP, positive end-expiratory pressure; CPAP, continuous positive airway pressure.

*Chest x-ray study or computed tomography scan.

†If altitude is higher than 1000 m, the following correction factor should be used: $\text{PaO}_2/\text{FiO}_2 \times (\text{barometric pressure}/760)$.

‡This may be delivered noninvasively in the “Mild” group.

From The ARDS Definition Task Force. Acute Respiratory Distress Syndrome—The Berlin definition. JAMA 2012;307(23):2526-2533.

Despite the lack of information about stress and strain in each individual patient, most available data strongly suggest that a gentle ventilation is safer than the application of high volumes and pressures. This evidence does not mean that 6 mL/kg ideal body weight represents the ideal tidal volume. In a patient with a very small baby lung, it still may be harmful, inducing excessive strain, whereas if applied to a lung characterized by a large ventilatable area, it may be low. There is little doubt, however, that 12 mL/kg ideal body weight is excessively high and unnecessary. It is evident that low tidal volume ventilation, decreasing the global alveolar stress and strain, is advantageous compared with high tidal volume ventilation in different patients.

It has been suggested that a plateau pressure of 30 cm H_2O represents the safe limit for plateau pressure.⁶¹ In a retrospective analysis, such a safe limit has been challenged, however.⁶² This is understandable if we consider that the airway plateau pressure is a poor surrogate of stress owing to the high variability of the chest wall compliance. The same plateau pressure, 30 cm H_2O , may result in completely different stress values in different patients.

SETTING POSITIVE END-EXPIRATORY PRESSURE

The available evidence on the effects of higher versus lower levels of PEEP in ALI/ARDS patients is summarized in Table 11.3. As shown, despite the fact that the experimental data

ALI/ARDS, acute lung injury/acute respiratory distress syndrome; NS, not significant; PEEP, positive end-expiratory pressure; P flex, lower inflection point of the pressure-volume curve of the respiratory system.

Studies cited in this table can be found in the complete list of references for the chapter, available online at www.expertconsult.com.

provide striking evidence that PEEP may reduce the damages of mechanical ventilation, the largest studies comparing higher versus lower PEEP levels in unselected ALI/ARDS patients were unable to find any difference in outcome.⁶³⁻⁶⁶

It has been suggested that PEEP should be of benefit in patients with higher lung recruitability and useless or harmful in patients with low lung recruitability.⁶⁷ Actually two meta-analyses seem to confirm this hypothesis. The meta-analysis by Phoenix and associates⁶⁸ showed a trend toward improved survival in the high PEEP group with no evidence of increase in barotrauma. The other meta-analysis by Briel and colleagues⁶⁹ on the largest three trials reported no treatment effect on hospital survival between higher and lower PEEP groups while a significant improved survival rate was found in patients in presence of ARDS defined as Pao₂/Fio₂ ratio equal or less than 200. In contrast, in patients with mild and moderate ARDS, higher PEEP seemed harmful. These results roughly account for what we know about the ARDS pathophysiology. In fact, the putative beneficial effect of PEEP on survival should be related to the prevention of excessive regional stress and strain by keeping open lung regions that would otherwise collapse.^{26,70} When we studied lung recruitability in an unselected ALI/ARDS population, we found that it varied from 0% to more than 50% of the whole lung.⁵⁹ We found that severity of lung injury was associated with higher lung recruitability and more severe hypoxemia, greater deadspace, and lower compliance of the respiratory system. By arbitrarily dividing the study population into patients with higher or lower lung recruitability, we first observed that in the latter, the amount of recruitable lung was almost negligible, amounting to about 50 g of

tissue weight. The response to the application of higher levels of PEEP was minimal and much lower than that observed in patients with higher lung recruitability.

SETTING RESPIRATORY RATE

Although extensive work has been devoted to understanding better how to set tidal volume and PEEP in ARDS, the potential importance of respiratory rate in the development of VILI has been scarcely investigated. Technology allows the use of respiratory rate from near zero breaths per minute using extracorporeal techniques to remove CO₂ to 2000 to 3000 breaths per minute, by employing high-frequency oscillation. Each tidal volume delivered may be considered as a stress cycle. Increasing the number of stress cycles may increase the lung damage. In experimental ARDS models, it has been observed that decreasing the respiratory rate decreases edema formation in isolated rabbit lung,⁷¹ whereas an increase in respiratory rate, during spontaneous breathing, leads to an increase in edema formation.⁷² It is conceivable that the respiratory rate may play a role in the pathogenesis of VILI when associated with a harmful tidal volume or inadequate PEEP. A different issue is the use of high-frequency oscillatory ventilation (HFOV), a technique that uses very high respiratory frequencies in association with very low tidal volumes and very high mean airway pressure, minimizing inspiratory overdistention and end-expiratory lung collapse.⁷³ Most patients treated with HFOV improved Pao₂/Fio₂ ratio and reduced oxygenation index over time. Clinical trials were not able to prove a survival benefit, however, a recent meta-analysis on six randomized

controlled trials comparing HFOV to conventional ventilation suggested a survival benefit at 30 days.⁷⁴ Two clinical trials are currently ongoing with the aim of comparing HFOV with lung protective mechanical ventilation (OSCAR trial in the United Kingdom [ISRCTN10416500] and OSCILLATE trial in Canada [ISRCTN87124254]). In the absence of definitive evidence HFOV remains investigational for routine management of ARDS and should be reserved for patients unresponsive to conventional ventilator strategies.

SETTING INSPIRATORY-TO-EXPIRATORY RATIO

Mechanical ventilators provide a wide range of inspiratory-to-expiratory (I:E) ratios. Setting an adequate I:E ratio may be of great importance when ventilating patients with structural alterations of lung parenchyma, such as chronic obstructive pulmonary disease and emphysema, and during asthmatic exacerbation. In these conditions characterized by a time constant of the respiratory system greater than normal, a longer expiratory time must be provided to allow deflation of gas from the lungs before the next respiratory cycle, avoiding dynamic hyperinflation and intrinsic PEEP.⁷⁵ During ALI/ARDS, no convincing evidence has been provided for the advantages of setting an I:E ratio different from 1:1.

In the past, inverse ratio ventilation⁷⁶ was advocated as a tool to improve the effects of mechanical ventilation in ARDS.⁷⁷⁻⁷⁹ Studies primarily showed an improvement of arterial oxygenation. Increased mean airway pressure, intrinsic PEEP, and a decrease in cardiac output were problematic.⁸⁰ Extreme forms of manipulating I:E ratio are not recommended; an I:E ratio in ALI/ARDS of 0.5 to 1.5 is appropriate.

INDIVIDUALIZING MECHANICAL VENTILATION IN PATIENTS WITH ACUTE RESPIRATORY DISTRESS SYNDROME

General principles underlying the application of mechanical ventilation in ALI/ARDS patients have been discussed. We now present the sequence of interventions that we believe are most appropriate for tailoring mechanical ventilation in an individual patient.⁸¹

The first intervention after admission to the ICU is to determine whether the patient has the criteria for ARDS diagnosis, keeping in mind that this syndrome consists of diffuse inflammatory lung edema. Patient history (research for possible etiologic factors leading to ARDS) and clinical observation (cyanosis, higher respiratory rate, use of accessory respiratory muscles, inspiratory crackles at lung auscultation mainly in the dependent lung regions) may suggest a possible lung inflammatory edema. Blood gas analysis and chest x-ray studies may confirm the initial diagnosis of the syndrome. The choice between an attempt of noninvasive respiratory support (facemask continuous positive airway pressure or noninvasive ventilation) or endotracheal intubation should be made on a clinical basis, according to the severity of illness, and whether the patient is stable or deteriorating. We pay particular attention to the improvement of P_{aO_2} after oxygen administration and to P_{aCO_2} . The lack of remarkable response in oxygenation to increased

F_{IO_2} indicates a remarkable fraction of right-to-left intrapulmonary shunt, which is typical of ARDS. Low P_{aCO_2} suggests that the respiratory muscles of the patient are still able to deal with the decreased compliance of the respiratory system (i.e., sustaining the increased respiratory effort), whereas normal or high levels of P_{aCO_2} suggest a near exhaustion of the respiratory muscles and need of immediate ventilatory support.

Clinicians should be aware of the immediate possible consequences of intubation and initiation of mechanical ventilation. Sedation, either by itself or in association with muscle paralysis, produces a loss of respiratory muscle tone and a cranial shift of the diaphragm, promoting further lung collapse with immediate consequences in gas exchange. Mechanical ventilation produces an increase in intrathoracic pressure and decreased venous return. The intravascular volume status of the patient should be assessed before intubation, and hypovolemia should be corrected. The rate and the amount of fluid replacement should be decided for each individual patient. Inadequate fluid replacement may lead to a severe hemodynamic impairment immediately after beginning positive-pressure ventilation. An excessive fluid replacement in an inflamed lung with leaking capillaries may result in a dramatic increase of pulmonary edema with devastating consequences on gas exchange. Wiedemann and coworkers,⁸² in a study published in the *New England Journal of Medicine*, compared a conservative and a liberal strategy of fluid management in 1000 patients with ALI. Although the primary end point (60-day mortality) was not significantly different, patients treated with the conservative strategy had better lung function and shorter duration of mechanical ventilation and intensive care without increasing nonpulmonary organ failures. For these reasons, we prefer to tailor fluid replacement according to the results of a fluid challenge test. Echocardiography also may be helpful in assessing the volumetric status.⁸³ After endotracheal intubation, the initial ventilatory setting employed is blind because the pathophysiologic characteristics of the patient have not yet been assessed. We usually set the ventilator (volume controlled) with a tidal volume equal to 6 to 8 mL/kg ideal body weight, F_{IO_2} equal to 0.7, and a respiratory rate of 15 breaths per minute, with an I:E ratio of 1:1. As soon as hemodynamic stability is obtained, a PEEP trial (preceded by a recruitment maneuver) is performed by applying in a random sequence of 5 to 15 cm H_2O PEEP with the patient under sedation and, sometimes, muscle paralysis. At each level of PEEP, we maintain tidal volume, respiratory rate, F_{IO_2} , and I:E ratio constant for about 20 minutes, after which we measure (1) arterial oxygenation, (2) respiratory system compliance, and (3) alveolar deadspace. Patients who, after the application of higher PEEP, improve at least two of these three parameters have a greater likelihood of having a higher lung recruitability. Alternatively, it is possible to target a specific saturation on the basis of pulse oximetry, if available, aiming at a hemoglobin oxygen saturation of 90%.

The improvement in arterial oxygenation alone, although commonly employed, may be misleading for the assessment of lung recruitment because it may be the result of a slight decrease in cardiac output or a modification of regional distribution of pulmonary blood flow or both. It has been shown that improvement in respiratory physiologic variables from a PEEP trial has low sensitivity (71%) and specificity

(59%) in assessing lung recruitability;⁵⁹ we prefer to obtain whole-lung CT scanning. In the CT scan facility, while maintaining the baseline ventilator setting, whole-lung CT scanning is performed at 5 cm H₂O PEEP at end expiration and 45 cm H₂O at end inspiration. The subsequent quantitative analysis of the CT scans allows us to obtain a precise assessment of lung recruitability. In patients with higher recruitability we apply PEEP greater than 15 cm H₂O, up to 20 cm H₂O and exceptionally greater than 20 but not exceeding 25 cm H₂O, whereas in patients with lower lung recruitability we apply a PEEP level not greater than 10 cm H₂O.

If CT scan is unavailable, and only the PEEP trial has been performed, we assign to the high-recruitment group patients with either a baseline Pao₂/Fio₂ ratio less than 150 when measured at 5 cm H₂O PEEP or patients who respond to 15 cm H₂O PEEP compared with 5 cm H₂O with a positive response of two of the following three variables: increased Pao₂, decreased alveolar deadspace, or increased compliance of the respiratory system.

We attempt to keep the plateau pressure less than 30 cm H₂O by modifying tidal volume and respiratory rate. As discussed earlier, however, tidal volume and plateau pressure are inadequate surrogates for alveolar stress and strain. We now measure, in each severe ARDS patient, the transpulmonary pressure by helium dilution technique, by employing an esophageal balloon (lung resting volume of 0 cm H₂O or 5 cm H₂O PEEP). With mechanical ventilation, a global pulmonary strain greater than about 1.5 (strain is dimensionless because it is the ratio of two volumes), or an end-inspiratory transpulmonary pressure greater than 20 cm H₂O, may cause VILI, with irreversible respiratory failure to follow.^{11,29} These values of alveolar stress and strain are the ones at which the residual ventilatable lung reaches its near total lung capacity, with a full extension of the collagen fibers of the lung skeleton.

In some patients, we have observed that a tidal volume of 8 to 10 mL/kg ideal body weight determines a lung strain value less than 1 and a transpulmonary pressure value less than 14 cm H₂O. In these patients, we employ a tidal volume greater than 6 mL/kg ideal body weight, avoiding excessive hypercapnia or need for sedation. In contrast, in the most severe patients, in which the baby lung is extremely small, even a ventilation with 6 mL/kg ideal body weight may result in values of alveolar stress and strain higher than those required to reach total lung capacity. Evidence from the literature and physiologic reasoning strongly indicate that for these patients a safe form of mechanical ventilation does not exist.^{84,85} We reserve to them the use of extracorporeal support. We acknowledge that measuring alveolar stress and strain may seem to be a physiologic curiosity or a research tool. Nonetheless, we have introduced them in our clinical practice as the most logical approach for VILI prevention.

Some authors advocate the use of other forms of mechanical ventilation in patients with ARDS.^{86,87} The rationale of pressure support ventilation in ARDS relies on the possibility of decreasing the need for sedation, while preserving the contribution of spontaneous breathing, and with possible advantages on gas and flow pulmonary distribution.⁸⁸ During the full-blown phase of the illness, we prefer to keep the patient well sedated. This approach may help to reduce energy requirement and oxygen consumption and CO₂ production.

The onset of recovery is characterized by the control or reversal, or both, of the cause of ARDS. An increase of systemic oxygenation and respiratory system compliance follows. When a Pao₂ value greater than 80 mm Hg is obtained at Fio₂ of 0.4, we start the weaning from PEEP application, decreasing the PEEP level no more than 1 cm H₂O every 4 to 6 hours, and suspending the process if the oxygenation consistently deteriorates. Subsequently, after an appropriate adjustment of sedation, we shift from pressure-controlled or volume-controlled to pressure-support ventilation, initially setting the support at the same inspiratory pressure used during controlled ventilation. According to the patient's response, pressure-support level is progressively decreased, and the final phase of weaning is initiated at pressure support of 5 to 10 cm H₂O, Fio₂ lower than 0.4, and PEEP level equal to 5 cm H₂O.

POSSIBLE ADJUNCTS TO MECHANICAL VENTILATION

PRONE POSITION

Prone positioning, first proposed in 1974⁸⁹ and first applied in ARDS patients in 1976,⁹⁰ results in improved arterial oxygenation in most patients. After the introduction of CT scanning, showing lung consolidation located in the dependent lung regions and the aerated baby lung in the nondependent lung regions,^{12,16} we integrated prone positioning as standard practice in clinical treatment of ARDS patients to improve systemic oxygenation.⁹¹ The initial hypothesis was that better perfusion of the baby lung, located in the dependent lung regions after prone positioning, would provide advantages in gas exchange. The picture observed was quite different, however. We did observe an improvement in arterial oxygenation, but the mechanism was likely different because CT scans taken in the prone position showed a density redistribution toward the dependent lung areas.⁹²

This observation led to our introduction of the "sponge model" as our pathophysiologic understanding of ARDS.⁹³ Whatever the position of the patient, the increased weight of the nondependent lung tissue squeezes the gas out of the dependent regions of the lung.⁴² The mechanisms of improved gas exchange were different from that first hypothesized. It is not the aim of this chapter to discuss the possible physiologic mechanisms of prone positioning, which may be found elsewhere.⁹⁴⁻⁹⁸ Taken together, all of the studies, including small and large series of patients, consistently showed that in 70% of the patients systemic oxygenation improves in prone compared with supine positioning,^{98,99} without any change in the applied airway pressure. There is no doubt that in life-threatening severe hypoxemia a trial in the prone position is indicated.

A different issue is the effectiveness of the prone position in improving ARDS outcome. Is mechanical ventilation in ARDS less harmful in the prone compared with the supine position? Does mechanical ventilation induce less alveolar stress and strain in the prone position? There is a consistent physiologic rationale to believe that this is the case. In experimental settings¹⁰⁰⁻¹⁰³ and in normal subjects and patients affected by ARDS, CT scan shows a more homogeneous distribution of gas throughout the lung parenchyma

in the prone compared with the supine position.⁹⁸ This observation strongly suggests that the distribution of alveolar stress and strain is more homogeneous in the prone position. In experimental models of ARDS, there is evidence that prone positioning prevents or significantly delays the development of VILI.^{103,104} Two large randomized studies on prone positioning were unable to show a significant benefit on outcome;^{97,105} however, prone positioning was applied for only about a quarter of the day, and mechanical ventilation was not controlled. In a more recent trial,¹⁰⁶ in which prone positioning was applied for 20 hours per day and mechanical ventilation was strictly controlled, a positive benefit was found for the patients treated with prone positioning. On these bases the Prone-Supine II study¹⁰⁷ was organized to detect potential survival benefit of prone positioning avoiding the limitations of previous trials. Although, the study was not able to show a significant survival benefit in the general population, a favorable trend was detected in the subgroup of patients with severe ARDS. In a meta-analysis including 10 clinical trials on adults and children Sud and associates¹⁰⁸ found that prone ventilation reduced mortality rate in severely hypoxemic patients ($\text{PaO}_2/\text{FiO}_2 \leq 100$, $p = 0.01$) but not in patients with $\text{PaO}_2/\text{FiO}_2$ greater than 100 ($p = 0.36$). The authors' suggestion was that prone position may provide benefits in severely hypoxemic patients, but it should not be routinely used in all patients affected by acute hypoxemic respiratory failure. In a pooled analysis¹⁰⁷ of the four largest databases^{99,105-107} of trials on prone position, the absolute mortality rate reduction in severe ARDS patients treated in prone position was approximately 10% (log-rank = 0.03). On the contrary, in patients with moderate ARDS prolonged prone position may be useless or possibly harmful.

EXTRACORPOREAL SUPPORT

Extracorporeal support of ARDS was first applied in 1972.¹⁰⁹ The first randomized trial ever performed in ALI/ARDS showed that patients treated with extracorporeal support or with conventional ventilation had similar mortality rates, equal to about 90%.¹¹⁰ In the 1980s, our center introduced extracorporeal CO_2 removal in ARDS, aiming at lung rest with a suggestion of benefit.^{111,112} A randomized study performed in 1994 did not show any survival benefit with extracorporeal CO_2 removal support.¹¹³ The results of this trial may have been significantly influenced by bleeding complications in patients undergoing extracorporeal CO_2 removal. Despite the discouraging results, in Europe few centers continued to use veno-venous extracorporeal support as a last resource in selected series of patients.¹¹⁴ In the United States, Bartlett and colleagues^{115,116} continued to provide extracorporeal support associated with mechanical ventilation with less strict entry criteria and with encouraging results. The interest on extracorporeal membrane oxygenation (ECMO) renewed after the publication of CESAR trial in 2009,¹¹⁷ which showed clear benefits on outcome when severely hypoxemic patients were treated with extracorporeal support in an expert high case volume center when compared to nonspecialized hospitals. The rebirth of the technique, however, occurred with its use as a rescue therapy during H1N1 flu epidemics in Australia and New Zealand in severely hypoxemic patients untreatable with conventional

methods.¹¹⁸ The approach was veno-venous with high blood flows. This report showed a survival rate higher than 70%, and an impressive number of centers in Europe, United States, South America, Canada, and Asia started to use ECMO in severely hypoxemic patients who do not receive benefits from maximal mechanical ventilation.¹¹⁹⁻¹²⁴ Survival rate ranged between 56% and 79%.

The impressive diffusion of ECMO led to the great improvement of this technology, and there are increasing numbers of reports describing simple forms of extracorporeal support, primarily aiming at CO_2 removal.¹²⁵ The actual indications for ECMO depend on the patient's need and the physician's request. The choice of the technique may vary from low-flow bypass with CO_2 removal to high-flow ECMO with total oxygenation support. If the aim is the treatment of life-threatening hypoxemia, the clear-cut indication is high-flow veno-venous ECMO. If the patient, however, presents with severe cardiac failure, veno-arterial ECMO must be used.

A simplified schema of the possible intervention is reported in Figure 11.6, which underlines the recent ARDS Berlin definition, which may be helpful in dictating the sequence of possible intervention when ARDS severity is increasing.

Therapeutic Options According to the Berlin Definition

	ARDS		
	MILD	MODERATE	SEVERE
ALTERNATIVE TREATMENTS			ECMO
	ECCO ₂ -R		
			Neuromuscular Blockade
			Prone Position
Airway Plateau Pressure	≤30 cm H ₂ O		
Transpulmonary Pressure	≤20 cm H ₂ O		
PEEP	≈10 cm H ₂ O	>15 cm H ₂ O	
Tidal Volume	6 mL/kg IBW		
Strain	≤1.5-2		

ARDS, acute respiratory distress syndrome; ECMO, extracorporeal membrane oxygenation; ECCO₂-R, extracorporeal CO_2 removal; PEEP, positive end-expiratory pressure; IBW, ideal body weight.

Modified from the Berlin definition of ARDS: an expanded rationale, justification, and supplementary material. Epub 2012 Aug 25. Erratum in: *Intensive Care Med.* 2012 Oct;38(10):1731-1732.

Figure 11.6 Simplified schema of possible ARDS intervention. ARDS, acute respiratory distress syndrome; ECMO, extracorporeal membrane oxygenation; ECCO₂-R, extracorporeal CO_2 removal; PEEP, positive end-expiratory pressure; IBW, ideal body weight.

KEY POINTS

- The targets of mechanical ventilation in ARDS have shifted from providing normal gas exchange to protecting the lung from VILI.
- Mechanical ventilation replaces the action of the respiratory muscles. The driving force of mechanical ventilation (airway pressure displayed on the ventilator) is spent partly to overcome the resistances to flow, partly to inflate the lung, and partly to inflate the chest wall.
- The distending force of the lung (the trigger of VILI) is the transpulmonary pressure (Pl)—the difference between the airway pressure (Paw) and the pleural pressure (Ppl). For the same driving force, in normal conditions, the transpulmonary pressure equals the driving force multiplied by the ratio between the lung elastance and the respiratory system elastance (lung elastance + chest wall elastance): $Pl = Paw \times EL/El_{tot}$. In normal subjects, this ratio is approximately 0.5; in ARDS patients, it may be 0.2 to 0.8. Consequently, the airway pressure alone may be misleading to assess the transpulmonary pressure imposed on the lung by mechanical ventilation (i.e., to assess the stress). We used airway pressure to indicate end-inspiratory pressure.
- The delivered tidal volume increases the lung volume and in the process produces strain on the lung. The ratio of change in lung volume over resting lung volume ($\Delta V/V_0$) is a rough approximation of the strain. Excessive strain causes shape changes of endothelial and epithelial cells inducing an inflammatory reaction. Because the resting volume (V_0 , the baby lung) may vary largely in ARDS, the same tidal volume per ideal body weight may induce largely different strain values.
- Stress and strain, the triggers of VILI, are linked by a constant, specific lung elastance (Espec), accounting for the following relationship: $Pl \text{ (stress)} = E_{spec} \times \Delta V/V_0 \text{ (strain)}$. The specific lung elastance is similar in normal subjects and in ARDS patients.
- Physiologic variables are generally poor indicators of the severity of lung injury, with the alveolar deadspace being the only variable associated with outcome. The severity of lung injury may be assessed by CT scan. The fraction of nonaerated lung tissue is strongly associated with mortality risk. The greater the lung injury, the smaller the baby lung, and the greater the stress-strain induced by mechanical ventilation.
- Among outcome studies testing different tidal volumes, only the study comparing the two extreme values tested (6 mL/kg versus 12 mL/kg) showed a significant benefit of lower tidal volume. Data from clinical studies and rationale from physiologic studies are strongly in favor of using the lowest tidal volume possible, likely associated with lower stress and strain, accepting hypercapnia as a side effect.
- All studies comparing lower versus higher PEEP randomly applied to *unselected* ARDS populations failed to show benefits on survival. In contrast, benefits of higher PEEP were found in more severe *selected* ARDS patients.
- The lung recruitability may vary greatly within the ARDS population (5% to 50% of the lung parenchyma) and is correlated with the overall lung injury severity. Higher PEEP possibly should be reserved only for patients with higher recruitability.
- When treating patients with ARDS, individual characteristics (lung injury severity, gas exchange, lung mechanics, abdominal pressure) should be assessed to tailor the least harmful mechanical ventilation setting according to the available evidence and physiologic rationale, providing the lowest stress and strain possible.
- In the severe ARDS, in which mechanical ventilation is more harmful, associated therapy such as prone positioning and extracorporeal support must be sought.

Hemoptysis

DIAGNOSIS OF INFECTION

LUNG BIOPSY—SURGICAL AND TRANSBRONCHIAL

SPECIAL SITUATIONS

Immunocompromised Host

Thrombocytopenia

COMPLICATIONS AND DEATH

SUMMARY

Bronchoscopy plays an important role in the care of critically ill patients. Since the introduction of the flexible fiberoptic bronchoscope in 1968, flexible bronchoscopy has slowly gained importance as a diagnostic and a therapeutic tool. It has largely replaced rigid bronchoscopy in the intensive care unit (ICU) because of the lack of need for complete anesthesia, the ease of use, and the fact that with a flexible bronchoscope one can perform procedures on a critically ill ventilated patient through an endotracheal tube or tracheostomy tube.

Lung biopsy is often a procedure of last resort in a critically ill patient with lung disease who is not responding to therapy. Whereas many of these patients are on mechanical ventilation, the potential benefits of biopsy need to be carefully weighed against the potential risks.

This chapter will review bronchoscopy and lung biopsy in critically ill patients. By definition, a critically ill patient has one or more organs that are under stress and have limited functional reserve. Stresses that are usually well tolerated by healthy individuals may have serious or even fatal consequences for a patient in the ICU. This chapter will first review the physiologic stresses induced by bronchoscopy. It will then review diagnostic and therapeutic indications for bronchoscopy in the ICU. Finally, we will review the potential role of bronchoscopic and nonbronchoscopic approaches to lung biopsy.

FIBEROPTIC BRONCHOSCOPY-INDUCED PHYSIOLOGIC CHANGES

GENERAL CONSIDERATIONS

The act of cannulation of the airway is not a physiologically neutral event.¹⁻⁵ It stimulates both cardiovascular and respiratory responses. In the ICU, there are three common stimuli that provoke these reflexes: intubation, bronchoscopy, and suctioning. Even after the use of sedation and application of topical anesthesia, the passage of a bronchoscope through the larynx typically results in a 30% increase in mean arterial blood pressure and cardiac index, a 40% increase in heart rate, and an 86% increase in pulmonary arterial occlusion pressure.¹ The response seems to represent a reflex to mechanical stimulation of the larynx. A significant hemodynamic response occurs even when patients are anesthetized and paralyzed before the passage of a bronchoscope through the larynx and into the trachea, with conflicting data as to whether there is a difference in hemodynamic response between the nasal and the oral routes.^{3,4} Topical anesthesia of the upper airway with lidocaine attenuates (but does not ablate) the cardiovascular responses.^{3,5}

The significance of the cardiovascular changes associated with bronchoscopy is related primarily to their potential

impact upon the heart and the brain. The increase in rate-pressure product has the potential to cause cardiac ischemia in patients with limited cardiac perfusion. In one small study, 3 of 10 monitored patients undergoing bronchoscopy, all of whom were 55 years old or older, developed electrocardiographic changes of ischemia.² In another study designed specifically to look at older patients, the incidence of ischemia was 17%.⁶ Despite these findings, bronchoscopy has a low mortality rate from ischemia. In studies that have described complications from bronchoscopy (ranging from as few as 10 to as many as 48,000 procedures), the rate of death from ischemic events ranged from 0% to approximately 0.01%.⁶⁻¹¹

A second potential cardiac complication of bronchoscopy is the triggering of arrhythmias. One study looking specifically for arrhythmias during bronchoscopy found an 11% incidence of “major arrhythmias.”¹² As with ischemia, however, the reported mortality rate from arrhythmias has been very low; in two large studies of complications of bronchoscopy the mortality rate from arrhythmias ranged from 0% to 0.04%.^{10,11}

With respect to the brain, both bronchoscopy and endotracheal suctioning cause significant increases in intracranial pressure.^{2,13} Because mean arterial pressure and intracerebral pressure increase roughly in parallel, there is little overall change in cerebral perfusion pressure.^{2,13} This may explain why no adverse intracerebral sequelae have been reported despite the observed increase in intracerebral pressure.¹³ Nevertheless, we believe that close attention to intracerebral pressure is warranted whenever possible in brain-injured individuals undergoing bronchoscopy.

Bronchoscopy also affects the work of breathing, respiratory pressures, and lung volumes. Transnasal cannulation of the trachea leads to a decrease in inspiratory and expiratory flow, a decrease in vital capacity, and an increase in functional residual capacity.¹⁴ Bronchoscopy through an endotracheal tube in a sedated but not ventilated patient leads to significant further decreases in flows and vital capacity and a marked increase in the work of breathing.^{14,15}

BRONCHOSCOPY IN MECHANICALLY VENTILATED PATIENTS

Mechanical ventilation adds additional complexity to the physiologic effects of bronchoscopy. The details were elegantly delineated in a study by Lindholm and colleagues.¹⁵ The first notable change is a dramatic increase in upper airway resistance. Airway narrowing related to endotracheal tube insertion by itself increases airway resistance. The subsequent introduction of a bronchoscope through the endotracheal tube greatly increases that resistance. The actual degree of increased airway resistance observed is related to the cross-sectional areas of both the endotracheal tube and the bronchoscope being inserted.¹⁵ The increased resistance has implications for ventilator gas delivery. The first is a potential decrease in delivered volume. With a volume-cycled mode, pressure increases as needed to deliver the specified volume, but the set volume may not be delivered owing to a pressure pop-off set in the alarm/safety parameters of the ventilator. (Although peak pressures of 60 to 80 cm H₂O can be reached at the airway opening, note that

the pressure gradient from the proximal obstruction limits the pressure delivered to the lung parenchyma.¹⁵) With a pressure-cycled mode of mechanical ventilation, the increase in upper airway resistance caused by bronchoscopic cannulation leads to an immediate decrease in delivered volume, the severity of which again depends upon the cross-sectional diameters of both the endotracheal tube and the bronchoscope. This effect can be countered by raising the applied pressure and the associated inspiratory airway pressure.

Whereas the driving pressure for inspiratory volumes depends upon external force (generated by the ventilator), exhalation is largely dependent upon the passive recoil of the lungs. The increase in airway resistance caused by introduction of the bronchoscope into the endotracheal tube thus has a disparate and more potentially dramatic effect upon expiratory volumes than upon inspiratory volumes. Sequential delivered volumes may be incompletely exhaled, causing a gradual buildup of intrathoracic volume and intrinsic positive end-expiratory pressure (auto-PEEP). Lindholm and colleagues¹⁵ documented several cases of auto-PEEP greater than 18 cm H₂O. In one patient being bronchoscoped through an endotracheal tube with an internal diameter of 7 mm, auto-PEEP was recorded at 35 cm H₂O.

Suctioning adds another layer of complexity. In addition to the cardiovascular changes stimulated by suctioning mentioned earlier, suctioning can cause profound changes in intrathoracic pressures and lung volumes. Not only can the auto-PEEP induced during bronchoscopy be eliminated, but with prolonged suctioning negative intrathoracic pressure can be created.¹⁵ This can lead to clinically relevant decreases in functional residual capacity, tidal volume, and minute ventilation, with potential for alveolar collapse, hypercarbia, and hypoxemia.

HYPOXEMIA

That bronchoscopy can cause hypoxemia is clear. The degree of hypoxemia ranges from mild to severe, and a variety of potential mechanisms are involved. The administration of benzodiazepines and narcotics can cause hypoxemia and respiratory depression in normal volunteers,¹⁶ and one study showed a 35% incidence of desaturation after sedation even before bronchoscopy was performed.¹⁷ The desaturation may not be completely due to central nervous system depression; Chhajed and coworkers¹⁸ showed that hypoxemia during bronchoscopy could be corrected in most of their lung transplant patients by the insertion of a nasopharyngeal tube, indicating that in their population upper airway collapse was a major cause of hypoxemia. Apart from the effects of sedation upon oxygenation, bronchoscopy itself can cause hypoxemia. Changes in airway resistance and the impact of suctioning upon functional residual capacity are probably major factors.¹⁹⁻²² Higher incidences of hypoxemia have been shown to correlate with the degree of prebronchoscopy pulmonary impairment, extent of suctioning, and performing a bronchoalveolar lavage (BAL).²⁰⁻²⁵ Furthermore, the hypoxemia induced by bronchoscopy often does not resolve immediately upon removal of the bronchoscope; it can persist for more

than 2 hours.^{17,24,25} Hypoxemia represents another stress on top of the cardiovascular reflex changes cited earlier and may negatively impact organs at risk. Hypoxemia may play a significant role in cardiac ischemia and arrhythmias associated with bronchoscopy.¹

Bronchoscopy through the endotracheal tube of a patient on a ventilator has been reported to cause an increase in PO_2 with an increase in PCO_2 and a decrease in PO_2 with no change in PCO_2 .^{14,15} The seemingly contradictory differences in findings probably reflect individual differences in how much patients are suctioned and the degree to which suctioning impacts functional residual capacity.

SUMMARY

In summary, bronchoscopy and other airway cannulations almost always trigger a reflex response that includes tachycardia and an increase in blood pressure. Bronchoscopy frequently causes hypoxemia, which may be of prolonged duration. For patients on ventilators, disparate physiologic changes can be created based on the mode of ventilation, the size of the endotracheal tube, the size of the bronchoscope, the duration of suctioning, and the flow rate that the suction channel of the bronchoscope is able to attain. Bronchoscopy can cause significant physiologic stress, and the critically ill patient may be less able to tolerate that stress than an otherwise healthy individual.

AIRWAY EVALUATION AND MANAGEMENT

INTUBATION AND ENDOTRACHEAL TUBE MANAGEMENT

Bronchoscopy can be an asset in the insertion and subsequent management of endotracheal tubes.^{26,27} For patients with difficult airways, an endotracheal tube can be placed over a bronchoscope and slid into the trachea after direct visual intubation with the bronchoscope. A similar technique can be used for changing the endotracheal tube in a tenuous patient, especially if switching from nasal to oral or oral to nasal.²⁷ Bronchoscopy is valuable in the placement of tubes for single-lung ventilation or placement of double-lumen tubes.²⁷ Bronchoscopy also allows the bronchoscopist to position the tip of an endotracheal tube at a point approximately 2.5 cm above the carina under direct visualization or, when there is a process such as tumor compression of the trachea, to place the tube wherever needed for optimal ventilation.²⁶

PERCUTANEOUS DILATIONAL TRACHEOSTOMY

Percutaneous dilational tracheostomy (PDT) has emerged as a primary method of tracheostomy for ICU patients. It has a lower incidence of overall complications than does open surgical tracheostomy, and it can be performed at the bedside, avoiding the risks of transporting a critically ill patient.²⁸⁻³¹ It also is more cost-effective.²⁹ PDT can be performed not only by surgeons, but also by trained intensivists

and pulmonologists;³⁰ it has become a standard intensivist procedure in many institutions.^{32,33} Although its overall safety profile is better than for open surgical tracheostomy, PDT does have a higher risk of posterior tracheal wall injury and false passage.³⁴ Bronchoscopy can be combined with PDT to allow direct endobronchial guidance for the procedure. Bronchoscopy has been suggested by several authors to be an important safety factor in PDT,^{31,34-40} although its use is not universally practiced.^{32,41} Direct visualization is a protection against inadvertent tracheal injury and a means of assessing an injury for intervention should it occur.^{34,36,38} The most logical approach to PDT is a team approach⁴² with at least two principal operators—one managing the bronchoscope and endotracheal tube and the second working at the neck to insert the tracheostomy tube.^{31,34,39} The risk of using bronchoscopy for PDT is that of increased hypoventilation because the patient is being ventilated through the endotracheal tube during the procedure.³⁷ This can be obviated with the use of a pediatric bronchoscope for guidance; a large working channel is not needed for this application.

AIRWAY OBSTRUCTION AND ATELECTASIS

The upper airway can become obstructed via several mechanisms. Bronchoscopy is valuable in diagnosing all of them. When an endotracheal tube is inserted, it becomes part of the airway. Kinking of the endotracheal tube or luminal blockage by hardened, inspissated secretions causes the same physiologic problems as a primary tracheal process. Granulation tissue at the proximal end of a tracheostomy tube or at the distal end of a tracheostomy tube or endotracheal tube can cause obstruction and difficulty with inflation or deflation of the lungs. (This is much less common with endotracheal tubes than with tracheostomy tubes because of Murphy's eye, the distal side port, on endotracheal tubes.) Benign or malignant processes can cause strictures or compression of the trachea. Finally, edema of the vocal cords and periglottic structures can lead to upper airway obstruction that is not evident with an endotracheal tube in place but that can cause recurrent respiratory failure after extubation; performing extubation over a bronchoscope allows immediate evaluation of the upper airway as the endotracheal tube is withdrawn with immediate diagnosis of this problem.²⁷

Foreign bodies can cause obstruction at various points in the airways. Traditionally, rigid bronchoscopy was used for management of foreign bodies given its capacity for airway control and the availability of tools larger than those that can be passed through a flexible bronchoscope.⁴³ Flexible bronchoscopes are the only choice, however, in an intubated patient, and the combination of larger channel scopes (2.8 mm and larger) for the passage of instruments and of different baskets and grasping tools makes flexible fiberoptic bronchoscopy a viable option in many cases.^{26,43,44} For nonintubated patients, a flexible bronchoscope through a rigid bronchoscope is sometimes an optimal approach.⁴³

Atelectasis is a common ICU problem and has been one of the most common indications for bronchoscopy in ICUs.^{45,46} The argument is obvious: If standard "blind" suctioning is effective and useful, why not use suctioning under

direct visualization for local airway obstruction due to secretions? One key study done by Marini and coworkers⁴⁷ challenged the assumption that bronchoscopy is an optimal approach to atelectasis. In their study of patients with radiologically evident atelectasis, one group underwent a regimen of initial bronchoscopy followed by regular chest physiotherapy and a second group received regular chest physiotherapy alone followed by delayed bronchoscopy at 48 hours only if atelectasis persisted. The authors showed early bronchoscopy to be the inferior approach; there was no difference in rate or degree of improvement between the two groups, and bronchoscopy led to more significant decreases in oxygenation.⁴⁷ The authors also looked at the presence or absence of air bronchograms, postulating that patients with air bronchograms had more distal consolidation (as opposed to proximal obstruction causing atelectasis) and would be more refractory to any attempts to re-expand consolidated lung. Their results strongly supported their postulate.⁴⁷

These data are valuable and should lead to initial trials of chest physiotherapy in most cases of atelectasis, but they do not apply universally in clinical medicine. Some patients with chest trauma or spinal cord injury are not candidates for chest physiotherapy.⁴⁸ Patients with chest trauma or spinal cord injury are usually not candidates for chest physiotherapy. Some patients have atelectasis and a severe refractory hypoxemia as a result of shunting of blood through the atelectatic lung. In these patients, a 24-hour wait may be inappropriate, and bronchoscopy sometimes leads to marked improvement. Judicious use of bronchoscopy for atelectasis is thus a clinical decision involving the art of medicine.⁴⁸ Some patients with atelectasis have severe refractory hypoxemia as a result of shunting of blood through the atelectatic lung. In these patients, trying chest physiotherapy may be inappropriate because bronchoscopy often can lead to marked improvement almost immediately. Judicious use of bronchoscopy for atelectasis thus depends on the clinical situation. For patients who have a bronchoscope inserted for atelectasis, one technique that has been moderately successful is that of isolated segmental inflation; the bronchoscope or a ballooned catheter is wedged into the atelectatic segment, and pressure of at least 30 mm H₂O is applied through the bronchoscope or catheter.^{45,48} This focal approach is more rational for focal atelectasis than are recruitment maneuvers applied to the whole chest because recruitment maneuvers are more likely to overdistend compliant alveoli than to open atelectatic alveoli.⁴⁵

TRAUMA

The value of bronchoscopy for the evaluation of chest trauma was defined in a landmark paper by Hara and Prakash.⁴⁹ The authors looked at 53 cases of blunt trauma to the chest, neck, or both in which bronchoscopy was performed within 3 days of injury. Bronchoscopy was believed to be of clinical value in 53% of the 53 cases. They documented injury and tears of the upper and lower airways, contusion or hemorrhage, aspirated material, and plugging or secretions. Only one of eight major tracheal injuries was not completely diagnosed. These data give compelling evidence for visual bronchoscopic evaluation of the bronchial tree in all cases of significant blunt chest trauma.

SMOKE INHALATION

Inhalation injury is a unique form of trauma to the bronchial tree. Most inhalation injuries are due not to heat alone, but to the deposition in the bronchial tree of soot and gases, the products of combustion.⁵⁰ Early ventilatory support and aggressive pulmonary toilet probably improve outcomes for inhalation injury,^{51,52} but the severity of inhalation injury may not become fully manifest for up to 5 days (usually 3 days).⁵² Bronchoscopy has been advocated in the evaluation of patients with possible inhalation injury.⁵¹⁻⁵³ Some patients have mucosal injuries that are obvious to even an inexperienced bronchoscopist, but sometimes even when there is significant injury, the bronchoscopic appearance of the airways may be minimally abnormal. For patients who have relatively normal-appearing mucosae, biopsy specimens from segmental or subsegmental carinae can yield pathologic information that is predictive of the degree of inhalation injury (or lack thereof) and can be used to guide aggressiveness of management.^{51,52} Another tool for evaluation of inhalation injury is the ventilation-perfusion scan,^{50,53} but the objectivity and reproducibility of bronchoscopic endobronchial biopsy could lead one to argue that it should be the current standard of care for the diagnosis of possible inhalation injury.

HEMOPTYSIS

Hemoptysis can run the gamut from scant to massive. There are several definitions of massive hemoptysis, with varying quantities of blood specified over different intervals. The best definition of massive hemoptysis is functional: Massive hemoptysis is bleeding in quantities that threaten to cause death by asphyxiation from filling of the bronchial tree with blood or by exsanguination.^{54,55} Patients with massive hemoptysis should always be admitted to the ICU.

Bronchoscopy plays two roles in massive hemoptysis—diagnostic and therapeutic. Most authors recommend bronchoscopy as soon as possible to localize the site of bleeding.^{54,56} Rigid bronchoscopy and flexible bronchoscopy each have their advocates. The argument for rigid bronchoscopy is that it allows better visualization of the major airways, more aggressive suctioning, removal of clots, and local tamponade with packing materials.^{56,57} The argument for flexible bronchoscopy is that it does not require the operating room or general anesthesia, it allows more thorough evaluation of the bronchial tree, and it allows directed intubation.^{54,56} Intubation may be with a regular endotracheal tube in the trachea or in the left lung or with a double-lumen tube. (The right upper lobe takeoff is too proximal in the right bronchial tree to allow selective right main bronchus intubation.) If bleeding is too great, flexible bronchoscopy is of limited value; small amounts of blood can obscure the relatively small lens of a bronchoscope.⁵⁴ For massive hemoptysis, the goals of bronchoscopy are to identify the bleeding site and to stabilize the patient enough to allow arterial embolization, surgery, or a sequence of the two; embolization and surgery are usually the two most effective therapies. Several temporizing endobronchial therapies have been advocated: iced saline lavage, topical 1:20,000 epinephrine, endobronchial tamponade

with packing or a Fogarty catheter, and endobronchial laser therapy.⁵⁴⁻⁵⁶

DIAGNOSIS OF INFECTION

Bronchoscopy is a valuable tool for the diagnosis of pulmonary infection in a critically ill patient. A variety of organisms, including *Mycobacterium tuberculosis*, *Pneumocystis jiroveci* (formerly *P. carinii*), fungi, viruses, and bacteria, are capable of causing severe pneumonia in critically ill patients. Given the broad differential diagnosis, it is important to try to determine the specific cause. Bronchoscopy offers access to lower airway secretions, which can lead to accurate diagnosis, focused therapy, and sometimes the withdrawing of unnecessary therapy. BAL is the most useful diagnostic modality. BAL can be performed in a patient who cannot or will not produce expectorated sputum or who is intubated. BAL samples alveoli more reliably than induced sputum. BAL fluid also is helpful for a broader range of diagnoses than induced sputum. In some cases, BAL recovery of organisms is not adequate alone, and biopsy is needed to confirm tissue invasion.

For BAL, the bronchoscope is wedged into a peripheral airway, and aliquots of sterile saline totaling at least 120 mL are instilled to ensure that alveolar spaces are reached. **Box 12.1** summarizes the recommended method for BAL. Fluid retrieved via suctioning is sent for diagnostic studies. The BAL technique samples about 1 million alveoli, or 1% of the lung.⁵⁸ For some infections, the presence of an organism in the lung is pathognomonic for active infection, whereas for others quantitative cultures are needed to distinguish lower respiratory tract infection from upper airway contamination.

M. tuberculosis is a cause of pneumonia that should not be forgotten in critical care medicine. BAL is a sensitive tool

for the diagnosis of *M. tuberculosis*, one of the organisms whose presence always means active infection.^{59,60} BAL is more sensitive than gastric washings for the diagnosis of tuberculosis.⁶¹ BAL or protected specimen brushings are often positive in patients who have pulmonary tuberculosis but negative sputum smears,^{59,62,63} and BAL is also more sensitive than transbronchial biopsies for diagnosis of tuberculous pneumonia.⁶⁴ (For miliary tuberculosis, biopsy is of great value.⁶⁵) The addition of molecular techniques such as polymerase chain reaction (PCR) can further increase the sensitivity of BAL for *M. tuberculosis*.⁶⁶

P. jiroveci is a pathogen in immunocompromised individuals. Its incidence increased dramatically in the 1980s with the emergence of the acquired immunodeficiency syndrome (AIDS). In the 1960s and 1970s, only about 100 cases were diagnosed per year in the United States.⁶⁷ In the 1980s, thousands of cases were diagnosed.⁶⁷ Because the organism cannot be cultured, its detection depends on identification in respiratory secretions. BAL greatly increases the yield for *Pneumocystis* pneumonia over bronchial washings and brushings and is the diagnostic procedure of choice.^{64,68,69} As with *M. tuberculosis*, *P. jiroveci* is an organism that can sometimes be difficult to see on smears, especially in patients with *Pneumocystis* pneumonia who do not have AIDS or who have AIDS but have received inhaled pentamidine.^{70,71} PCR can increase the sensitivity of fluid examination with the caveat that some patients can have *Pneumocystis* colonization without infection, and the PCR method is sensitive enough to detect those cases.^{72,73} In patients without AIDS or patients with AIDS receiving inhaled pentamidine, transbronchial biopsy increases the diagnostic yield.^{70,74}

The diagnosis of fungal pulmonary infection is more problematic; some fungi can colonize the bronchial tree without being a cause of active infection. Fungal infection is a major issue in the immunocompromised host, but can occur in immunocompetent individuals and can be community-acquired.⁷⁵ *Candida* species often colonize the respiratory tract in critically ill patients; their isolation from BAL fluid alone is not diagnostic of tissue invasion.^{75,76} *Aspergillus* runs the gamut of possibilities; it can colonize the upper airways without infection, and it can be difficult to detect sometimes when it is the cause of deep tissue infection. In the appropriate clinical and radiologic setting, a positive BAL for *Aspergillus* would be a reasonable criterion for starting therapy, but a negative BAL for *Aspergillus* is inadequate to rule out infection.⁷⁷ PCR would seem promising to increase sensitivity for *Aspergillus*, but published results have been variable, and it is not a standard tool.⁷⁸⁻⁸⁰ Because of the possibility of colonization with *Aspergillus* and *Candida* species, lung biopsy showing tissue invasion is needed to confirm active infection by these fungi.^{76,80} In contrast, *Cryptococcus neoformans*, although ubiquitous, does not routinely colonize the respiratory tract; its detection in samples of lung fluid is strong presumptive evidence for an active role in pulmonary infection.^{81,82}

The endemic fungi, *Histoplasma capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis*, are capable of causing fulminant infection and cannot be ignored as diagnostic possibilities for pneumonia in patients who live in or travel through endemic areas.⁸¹⁻⁸⁶ Diagnosis is sometimes difficult, although the organism may be more plentiful and easier to identify in pulmonary secretions of patients who have

Box 12.1 Bronchoalveolar Lavage

- Wedge the bronchoscope into a peripheral area of whatever segment is most suspect radiologically. If there is no such segment, wedge into an upper lobe segment if *Pneumocystis* pneumonia is suspected or into a posterior lower lobe segment otherwise.
- Instill 30- to 60-mL aliquots of sterile nonbacteriostatic saline through the wedged bronchoscope until some fluid can be retrieved using suction. Discard approximately the first 20 mL of fluid.
- Attach a sterile specimen cup in line with the suction tubing, and instill further aliquots until at least 120 mL have been instilled and at least several milliliters of fluid have been obtained.
- Bilateral lavage has a higher yield than unilateral lavage.
- Have the fluid divided into two aliquots. One is plated using quantitative techniques; the second is centrifuged, stained, and examined for intracellular organisms and other diagnostic findings.
- Time from obtaining bronchoalveolar lavage fluid to plating of quantitative specimen should be <4 hours.

fulminant disease. BAL fluid has a much higher yield than sputum.⁸⁷ If organisms are not seen on smear, fungal cultures can take weeks, an unacceptable interval for seriously ill patients. For *H. capsulatum*, an antigen can be detected in bodily fluids (including BAL) and is of clinical value.⁸⁶ The other two endemic fungi are more problematic when not demonstrable on staining of fluids or biopsy material, but promising techniques with antigen detection, DNA probes, and PCR are evolving and should become clinically available soon.^{83,85,88,89}

Similar to fungi, viral pneumonias occur more frequently in immunocompromised hosts, but viruses play a role in community-acquired pneumonias as well.⁹⁰⁻⁹² In a multinational study, viruses alone were identified in 9% of community-acquired pneumonias, and viruses as co-pathogens were identified in an additional 9% of community-acquired pneumonias.⁹² Viral pneumonia is relevant to the critical care setting; in the multinational study, 8% of patients with pure viral pneumonia were admitted to the ICU owing to severity of disease.⁹² In another study using the most sensitive available virus detection technique, reverse transcriptase PCR, viruses were present as pathogens or co-pathogens in 23% of patients hospitalized for community-acquired pneumonia.⁹⁰ Analogous to the atypical pneumonias, no clinical characteristics reliably differentiate viral from bacterial pneumonia.^{90,92,93}

The virology of viral pneumonia is different for pneumonia in immunocompetent and immunocompromised hosts. In immunocompetent individuals, the most common viruses are influenza A and B, parainfluenza, respiratory syncytial virus, and adenovirus.⁹³ In immunocompromised patients, the herpesviruses—herpes simplex, varicella zoster, and cytomegalovirus—are most common, with adenovirus, respiratory syncytial virus, and measles also occurring.^{93,94} BAL is useful in the diagnosis of viral pneumonia; BAL fluid is an ideal substrate for most studies done to detect viral infection.^{95,96} For all but herpes simplex virus and cytomegalovirus, the presence of the virus is diagnostic of infection.^{95,97} Cytomegalovirus and herpes simplex virus can be present in BAL fluid in the absence of pneumonia; proof of tissue invasion is more specific for active infection.^{95,97} Viral pneumonias are often difficult to diagnose, and cultures can take days to weeks. Newer diagnostic techniques such as reverse transcriptase PCR offer a more sensitive diagnostic tool.⁹⁸

BAL is of major utility in the diagnosis of bacterial pneumonias. It has long been recognized that patients in the ICU often have colonization of the upper airways by several potentially pathogenic organisms, and that culture of upper airway secretions cannot be used to diagnose infections of the lower airways and lung parenchyma. Quantitative culture of BAL specimens has been proved to best obviate the issue of upper airway colonization, and BAL has thus emerged as the best currently available diagnostic test for bacterial pneumonia.^{58,99} An alternative to BAL is the protected specimen brush (PSB). BAL allows the sampling of a much larger area of lung than does the PSB and logically would be a better diagnostic modality. Although the two modalities are equally accurate in some studies, for several reasons BAL has become the diagnostic procedure of choice for bacterial pneumonia (Box 12.2).^{58,99} A third technique, the blind passage of a protected brush into the airways

Box 12.2 Reasons to Use Bronchoalveolar Lavage (BAL) Over Protected Specimen Brush for the Diagnosis of Lung Infiltrates

- BAL has a higher sensitivity.
- BAL is less expensive.
- BAL has a lower complication rate (pneumothorax or bleeding with protected specimen brush).
- BAL allows Gram stain of concentrated smear to look for extracellular organisms.
- BAL offers the opportunity to evaluate cells for intracellular organisms, additional proof of active infection.
- BAL is a tool for the diagnosis of infections other than bacterial infections.
- BAL yields specimens that can be used for probe techniques such as polymerase chain reaction.
- BAL is a tool for the diagnosis of other infiltrative processes (e.g., alveolar bleeding) that can mimic infection radiologically.

Data from references for this chapter (complete list available online).^{58,99,101}

without bronchoscopic guidance, has been described.¹⁰⁰ This technique has a relatively lower sensitivity than BAL, which probably depends on which lobe is most involved with infection. For example the catheter cannot be passed into the upper lobes.^{58,100} For this reason and the reasons cited in Box 12.2, BAL has evolved as the procedure of choice.⁹⁹

Two quantitative methods for bacterial growth of samples obtained by BAL have been described. The first is a simple log count; any bacteria present in greater than or equal to 10^4 colonies by quantitative methods is a pathogen unless proved otherwise.⁵⁸ (If PSB is used, a smaller area of lung is sampled and a concentration of $>10^3$ colonies is considered diagnostic of infection.⁵⁸) The second, called the bacterial index, was described by Johanson and colleagues.¹⁰¹ This method recognizes the fact that in careful studies numerous patients with pneumonia have more than one infecting organism.^{23,92,101,102} For the bacterial index, the log numbers of each cultured organism are summed (10^4 *Staphylococcus aureus* + 10^3 *Pseudomonas aeruginosa* = bacterial index of 7). With this system, a bacterial index greater than 6 is a sign of moderate to severe pneumonia.¹⁰¹ Although the bacterial index system seems more rational, single-organism quantification has become the de facto standard in current clinical practice.

Reinforcing the value of BAL for clinical management of bacterial infection is a study by Rodriguez and Fishman.⁷⁴ The authors performed quantitative cultures on BAL fluid and PSB from 32 ventilated patients not suspected to have pneumonia. There were six “false-positives,” with quantitative cultures in the pneumonia range. Four of the six patients subsequently developed clinical pneumonia.

If a patient with suspected bacterial pneumonia has already been given antibiotics, the quantitative culture of distal airway secretions loses sensitivity.^{103,104} A decrease in recovered organisms becomes significant within 12 hours of initiation of antimicrobial therapy and reaches 50%

between 24 and 48 hours.¹⁰⁵ This is not surprising because even quantitative cultures of lung tissue have a dramatic loss of sensitivity and specificity for patients who have received prior antibiotic therapy.¹⁰⁶ Despite this loss in sensitivity, BAL may make sense in the evaluation of critically ill patients with lung infiltrates who are receiving antibiotics as long as these limitations are recognized. BAL can detect organisms not being covered by the current antibiotic regimen, and BAL could help to define nonbacterial infectious agents or other noninfectious processes responsible for the clinical presentation.

When discussing the diagnostic utility of bronchoscopy for the diagnosis of severe lung infection, it is important to mention diagnoses that may be missed by the techniques discussed previously. The “atypical pneumonias”—principally *Legionella pneumophila*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae* and *C. psittaci*—can be community-acquired. The myth that “atypical” and “typical” pneumonias can be distinguished clinically has been refuted. *Legionella* is particularly capable of causing severe disease, and the other organisms can be present as coinfectants in severe disease.¹⁰⁷⁻¹⁰⁹ *Legionella* is not typically visible on Gram stain, does not grow on standard bacterial culture, and requires about 1 week to grow on special media when it is present. BAL material in a patient being evaluated for severe community-acquired pneumonia should be sent for direct fluorescent antibody staining for *Legionella* and for culture.¹¹⁰ The direct fluorescent antibody staining is reasonably sensitive and very specific for *Legionella*,¹⁰⁷ and direct fluorescent antibody staining of pulmonary secretions and of urine are the most rapid diagnostic tools available. The direct fluorescent antibody of pulmonary secretions remains positive for at least 48 hours after institution of appropriate therapy.¹¹⁰

There is an importance to negative BAL for quantitative bacterial culture. A prospective study comparing management based upon quantitative cultures from invasive diagnostic techniques (BAL or PSB) with management based upon clinical data without quantitative cultures showed that the patients whose therapy was started or withheld based on quantitative bacterial studies had less antibiotic use, lower mortality rate, and less sepsis-related organ failure.¹¹¹ The importance of negative bacterial studies lies not only in the capacity to withhold or discontinue treatment for bacterial pneumonia, but also in the implication that other types of pulmonary infection or injury should be sought and that, in some cases, extrapulmonary sources of bacterial infection may be present.^{58,111} The implications of BAL for a critically ill patient thus extend beyond the lungs.

In summary, bronchoscopic techniques for the diagnosis of pulmonary infection are valuable tools in intensive care medicine. BAL is the most valuable single tool, with diagnostic implications dependent on the organism being evaluated. It is important to remember that a wide spectrum of organisms can cause pneumonia in critically ill patients; the intensivist needs to consider tuberculosis, *Pneumocystis*, viruses, fungi, and atypical organisms in addition to typical bacteria.¹¹² When BAL fluid has been obtained, the diagnostic techniques of greatest value vary with the infecting organism. For some infecting organisms, detection of a causative organism can be difficult even in the presence of severe infection, and sensitive assays such as PCR can help

in the rapid detection of the causative agent. In other cases, such as bacterial infection, organisms abound and it can be difficult to separate colonization from infection; in these cases, quantitative cultures are of greatest value. For other organisms, tissue samples are needed for definitive diagnosis. Table 12.1 summarizes diagnostic methods relevant to different lung infections. BAL fluid is the optimal substrate for almost every listed study with the exception of titers and biopsy material.

LUNG BIOPSY—SURGICAL AND TRANSBRONCHIAL

The decision of whether or when to perform an open lung biopsy is difficult and a matter of debate. Open lung biopsy is the gold standard for the diagnosis of severe cryptogenic lung disease.^{113,114} When performed, it has a high diagnostic accuracy, although it is not 100% accurate; in one study with 25 patients who had biopsies and subsequent autopsies, the autopsy confirmed the open lung biopsy diagnosis in 76% of cases.¹¹⁵ Open lung biopsy is useful not only in the diagnosis of infection (particularly infections for which tissue invasion is essential to prove clinical relevance), but also in the diagnosis of primary lung involvement by diseases such as malignancy, nonspecific inflammatory lung disease, and lung-related toxicities of therapeutic interventions. Box 12.3 demonstrates the breadth of possible diagnoses that can be made with open lung biopsy after other diagnostic studies are negative.

Box 12.3 Diagnoses with Open Lung Biopsy After Other Studies Are Negative

Table 12.1 Diagnostic Techniques for Important Potentially Severe Pulmonary Infections

Important Organism	Presence in BAL Diagnostic?	Culture	Serology	Detection with Antibodies	Gene Amplification	Cytology/ Pathology/Other
<i>M. tuberculosis</i>	Yes	Usually positive—slow			PCR	Necrotizing granulomas
<i>Legionella</i>	Yes	Special media—slow	≥1:256 or 4-fold increase	IF of sputum or BAL	PCR±	DFA of urine or pleural fluid
“Typical” bacteria	No	BAL >10 ⁴ PSB >10 ³ BI >6				DFA—urinary pneumococcal antigen
Influenza virus (A, B, and C)	Yes	Positive—slow	4-fold increase	IF, ELISA (A and B)	PCR	Hemadsorption testing
Herpes simplex virus	No	Cell culture—cytopathic effects		IF, ELISA		Nuclear inclusions (Cowdry A bodies)
Cytomegalovirus	No	Cell culture—cytopathic effects		ELISA		Nuclear inclusions (“owl’s eye”)
Varicella-zoster virus	Yes	Cell culture—cytopathic effects				Nuclear inclusions (Cowdry A bodies) Typical rash helpful
Respiratory syncytial virus (rare)	Yes	Cell culture—cytopathic effects		IF	PCR	Tzanck preparation Eosinophilic cytoplasmic inclusions
Parainfluenza viruses (1-4)	Yes	Cell culture—cytopathic effects		IF	PCR	Hemadsorption testing Small eosinophilic cytoplasmic inclusions
Adenovirus	Yes	Cell culture—cytopathic effects		IF	PCR	Variable inclusion pattern
<i>Cryptococcus</i>	Yes	Slow				Antigen-serum Tissue invasion
<i>Aspergillus</i>	No					Tissue invasion
<i>Candida</i>	No					Tissue invasion
<i>Coccidioides</i>	Yes		High or increasing			
<i>Histoplasma</i>	Yes		≥1:64 or 4-fold increase	ELISA (cross-reacts with <i>Blastomyces</i>)		Can be hard to find even with culture Antigen-urine or serum Tissue invasion
<i>Blastomyces</i>	Yes			ELISA (cross-reacts with <i>Histoplasma</i>)		

BAL, bronchoalveolar lavage [fluid]; BI, bacterial index; DFA, direct fluorescent antibody; ELISA, enzyme-linked immunosorbent assay; IF, immunofluorescence testing (direct or indirect); PCR, polymerase chain reaction; PSB, protected specimen brush.

Open lung biopsy leads to a change in therapy in 57% to 75% of cases in which it is performed.^{113,114,116-118} Open lung biopsy can be performed in patients with respiratory distress and patients on ventilators with a reasonable rate of perioperative complications; death attributed to the biopsy procedure itself is rare, and complications such as persistent air leak usually resolve over time.^{114,116,117} Complication rates have been reported to be the same with video-assisted

thoracic surgery as with thoracotomy.¹¹⁸ Several recent studies have reported the frequent use of bedside open lung biopsy, which avoids transport of a critically ill patient and appears to have a morbidity rate similar to that of doing the biopsy in the operating room.¹¹⁸⁻¹²²

Although open lung biopsy sounds promising, it has several drawbacks. First, authors who separated open lung biopsy results into “specific” (allowing focused therapy

thought or known to have some efficacy) and “nonspecific” (a pattern of injury such as diffuse lung damage with no clear cause and no documented effective therapy) found that 38% to 46% of patients had nonspecific injury and no specific therapeutic benefit from the procedure.^{114,118} Second, mortality rate is extremely high in this group despite specific diagnoses and the previously mentioned changes in therapy, particularly if the patients have respiratory compromise; for those patients, the short-term mortality rate ranges from 52% to 70%.¹¹⁶⁻¹¹⁸ (Note that short-term mortality rate is believed by most authors to be related far more to the underlying disease than to the open lung biopsy procedure.¹¹⁶⁻¹¹⁸) Third, most patients already have received appropriate therapy; in most cases, the change in therapy would be discontinuation of unnecessary drugs or increased dosing of a drug already being given (usually steroids). In some, the benefit of open lung biopsy would be acknowledgment of end-stage disease and withdrawal of all therapy. The most important outcome of open lung biopsy would be a change in therapy that altered outcome from death to survival. Institution of a new potentially lifesaving therapeutic intervention as a result of open lung biopsy is uncommon.^{114,116,117} In 1988, Warner and colleagues¹¹⁷ discussed open lung biopsy in patients with respiratory compromise and said, “any complications of a procedure of unknown benefit is of concern.” Some authors hold this opinion to this day. Most patients have received anti-infective drugs or steroids or both before open lung biopsy is considered, and one could argue that most patients who could respond would have responded before open lung biopsy. Nevertheless, that the controversy is “alive and well” is illustrated by a quote from Chuang and associates:¹¹³ “It is not ethical to avoid open lung biopsy in patients with unclear diagnoses, as open lung biopsy is known to be the most sensitive and specific test available at this time.”

Another controversy with respect to open lung biopsy concerns when to perform it. Two groups have reported open lung biopsy relatively early in the course of respiratory failure with diffuse infiltrates and have withheld therapies until and unless biopsy results demonstrated a specific indication.^{121,122} Not unexpectedly, this approach led to a high number of new therapies, usually steroids or antiviral agents. Papazian and coworkers argued that their approach improved survival.¹²² The data provide valuable support for a counterargument—that all patients with idiopathic diffuse lung disease should be treated with both steroids and antiviral agents. If this had been done in these two series, the added benefit of open lung biopsy would have been very small.

Given the controversies and the available data, a few principles would seem appropriate in considering whether or not open lung biopsy should be performed. First, in most cases, BAL (and perhaps transbronchial biopsy; see later) should be performed before open lung biopsy is considered. Second, patients who have three or more organs failing (lung plus two more) probably should not undergo biopsy; the prognosis is too poor.¹¹⁴ Third, decisions about open lung biopsy should be based more upon the prior condition of the patient and the potential utility of the study than upon the degree of ventilatory distress or compromise of the patient; post-operative death related to the biopsy itself is rare. Open lung biopsy in a critically ill patient with

undiagnosed pulmonary infiltrates remains a valuable tool that is uncommonly indicated but that will occasionally provide a diagnosis that results in lifesaving therapy.

Bronchoscopic transbronchial lung biopsy may fill the gap between “nontissue” procedures such as BAL and open lung biopsy with its large amount of tissue for pathologic examination and culture. Open lung biopsy by definition requires anesthesia and by definition causes a breach in pleural integrity and requires chest tube placement, with many patients having air leaks after the procedure.¹¹⁶⁻¹¹⁸ Transbronchial lung biopsy requires only conscious sedation and would require chest tube placement only if a complication occurred, not as a matter of routine. As noted earlier in the discussion of infection, some diagnoses, such as invasive aspergillosis, *Candida* pneumonia, and cytomegalovirus pneumonia require tissue samples showing tissue invasion. Tissue samples can increase the diagnostic yield for other organisms such as *M. tuberculosis* and *P. jiroveci*.¹²³ Diagnoses such as cryptogenic organizing pneumonia and several others listed in Box 12.3 cannot be made without tissue. Transbronchial lung biopsy is reasonable with BAL or after a negative BAL in compromised patients with infiltrates of unknown cause.¹²³⁻¹²⁵ It was formerly thought that to perform transbronchial lung biopsy in a patient on a ventilator carried too high a risk of complications to be warranted.¹²⁶ The available data challenge this concept. Two early studies^{127,128} and several more recent studies^{69,125,129,130} have evaluated the yield and complications of transbronchial lung biopsy in ventilated patients. All of these studies showed high yields similar to the yields for open lung biopsy. The pneumothorax rates varied from 0% to 24%. Bleeding was considered to be significant in 6% to 20%, with all cases self-limited. No fatalities occurred. When transbronchial lung biopsy in ventilated patients is compared with open lung biopsy, for which general anesthesia, incisions, violation of the visceral pleura, and a chest tube are requisites, it is apparent that transbronchial lung biopsy is underused in this population; it has a favorable risk-to-benefit ratio.

SPECIAL SITUATIONS

IMMUNOCOMPROMISED HOST

Immunocompromise is a recognized risk factor for respiratory infection. Years of elegant work have helped to define classic types of immunocompromise and patterns of infection that are more typical for the different types.¹³¹⁻¹³³ Long-recognized diseases causing immunocompromise include solid tumors on chemotherapy, hematologic malignancies, organ transplantation, chronic diseases for which cytotoxic or steroid therapy is given, human immunodeficiency virus (HIV) infection, and other less common acquired or congenital diseases.^{126,133} Although immunocompromise definitely includes the preceding diseases, it has no clear boundaries. Patients with chronic insulin-dependent diabetes, alcoholics, patients with severe malnutrition, and patients on drugs such as infliximab, a tumor necrosis factor antagonist, almost certainly have degrees of immunocompromise that affect their susceptibility to infection.¹³⁴⁻¹³⁸ The stresses of critical illness and organ dysfunction coupled

with the broaching of natural defense systems (skin by central lines, lungs by intubation, urinary tract by catheters) put critically ill patients at increased risk for infection.

Many chronic illnesses probably also carry an increased risk for infection. Shelhamer and colleagues¹³³ recognized the difficulty with this issue and defined immunocompromise as “any condition, congenital or acquired, temporary or chronic, in which the response of the host to a foreign antigen is subnormal.” For patients with classic known forms of immunocompromise, special diagnostic attention has to be paid to the possibility of *Pneumocystis* pneumonia, invasive fungal infection, infection with the herpesviruses, and tuberculosis. Three factors make this area gray rather than black-and-white: (1) Lack of knowledge that a patient is immunocompromised does not rule out immunocompromise, (2) degrees of immunocompromise exist, and (3) most of the pathogens discussed are capable of causing disease in “normal” hosts. For these reasons, some specific issues related to immunocompromise have been mentioned throughout this chapter, but in the clinical approach to a patient with severe respiratory disease, it makes sense to assume that any patient might be immunocompromised; the diagnostic workup should, as mentioned, cast a wide net.

THROMBOCYTOPENIA

Thrombocytopenia is an obvious risk factor for bleeding from invasive procedures. BAL has been shown to be safe and clinically useful in thrombocytopenic patients.¹³⁹ Bronchoscopic procedures and open lung biopsies have been performed safely in patients with thrombocytopenia.^{118,140} Historically, procedures have been limited to BAL, or platelets have been given before bronchoscopic or surgical procedures.^{118,140}

COMPLICATIONS AND DEATH

The true incidence of complications of bronchoscopy in the ICU is poorly defined. Most reviews of the topic^{27,40,141-144} cite several older studies of bronchoscopy in general,^{7-9,11,145} not specifically in critically ill patients. The two largest and most-cited reports are by Credle and colleagues⁷ and Suratt and coworkers¹¹ and reviewed 24,521 (Credle) and “approximately 48,000” (Suratt) procedures. These were retrospective reports based on mailed questionnaires. Death rates were 0.01% and 0.03%.^{7,11}

The next largest study was a retrospective single-institution study of 4273 bronchoscopies, which reported 0% mortality rate and a 0.5% frequency of major complications (pneumothorax, bleeding, respiratory failure requiring intubation).⁹ Three prospective studies reported on 205 to 1146 flexible bronchoscopies and reported mortality rates of 0%,⁹ 0.1%,¹⁴⁵ and 0.5%.⁸ The highest reported mortality rate came out of a study from a consortium of expert bronchoscopists studying autofluorescence.¹⁴⁶ The study included the requisite of at least two endobronchial biopsies, and in a series of 300 cases the immediate postbronchoscopic mortality rate was 0.7%. Two retrospective studies^{46,147} and one prospective study⁶⁹ reviewed bronchoscopies performed specifically on patients in the ICU. No procedure-related

deaths were reported. Throughout these studies, only death rates are consistently noted; major and minor complications are variably defined.

Several principles emerge from the previously cited studies. The complication rates depend on the invasiveness of the procedure. The highest incidence of complications occurs with lung biopsy and then, in descending order, with brushings, BAL, and simple observation. For the patients expected to have the highest complication rate—patients on ventilators undergoing transbronchial biopsies—there is a pneumothorax rate of 24%, but no fatalities have been reported.^{69,125,127-130} None of those studies involved large numbers of patients; it is inevitable that fatalities would occur in this subset of high-risk cases. Nevertheless, many years of experience with flexible fiberoptic bronchoscopy have led to the conclusion that its benefits outweigh its risks. No bronchoscopy should be done on a critically ill patient without a reason, but when a reason is present, bronchoscopy is often the unique or the safest method known of obtaining data that may affect care.

SUMMARY

Since its inception in 1968, flexible fiberoptic bronchoscopy has evolved into a major tool in the evaluation and management of critically ill patients. The bronchoscope allows evaluation of and sometimes management of airway problems. The bronchoscope follows the most natural pathway into the lung—the airway—and allows sampling of secretions and tissues from the alveolar level. The basic techniques have been defined for many years. What has been refined is our understanding of their utility and testing methodologies; increasing sensitivities and specificities over the years have greatly enhanced our capacities, particularly in the diagnosis of lung infections. Some lung infections require lung tissue for definitive diagnosis, as do several diagnoses that can cause diffuse lung disease and can sometimes mimic infection. Open lung biopsy is a time-honored approach with high diagnostic accuracy that may sometimes be an optimal approach. Transbronchial lung biopsy, even in a ventilated patient, has a clinical impact similar to that of open lung biopsy and is probably underused in critically ill patients with diffuse infiltrates who are failing empiric therapies. It is clear that the more ill the patient, the higher the risk of any invasive procedure, but the literature points the risk-to-benefit ratio of bronchoscopy in favor of performing bronchoscopy for the indications outlined in this chapter.

KEY POINTS

- Bronchoscopy has become a major tool in the evaluation of the airways and lung parenchyma of critically ill patients.
- Bronchoscopy stimulates a series of reflexes affecting blood pressure, heart rate, and intracerebral pressure, but this is true for any cannulation of the upper airway (e.g., suctioning), and bronchoscopy for the evaluation

KEY POINTS (Continued)

- of lung problems in critically ill patients has a favorable risk-to-benefit ratio.
- Inserting a bronchoscope through an endotracheal tube causes upper airway obstruction and can cause hypoventilation or hyperinflation or both; the physiologic changes caused by the bronchoscope need to be understood and possibly compensated for.
- Bronchoscopy is a valuable tool for the diagnosis and management (especially intubation and percutaneous tracheostomy) of upper airway problems.
- Bronchoscopy with BAL is the most effective and accurate clinical tool currently available for the diagnosis of pulmonary infection in critically ill patients.
- The potential of bronchoscopy for the diagnosis of infection is being advanced at present not by bronchoscopic techniques but by the development and clinical application of extremely sensitive tools such as PCR assays.
- Critically ill patients with undiagnosed infiltrates occasionally benefit from lung biopsy; the results often affect management, but rarely affect outcome. Available data suggest that bronchoscopic transbronchial lung biopsy has yields similar to those for open lung biopsy with a more favorable risk-to-benefit ratio.

Noninvasive Respiratory Monitoring

Amal Jubran | Martin J. Tobin

CHAPTER OUTLINE

GAS EXCHANGE

Pulse Oximetry

Transcutaneous Blood Gas Monitoring

Capnography

RESPIRATORY NEUROMUSCULAR FUNCTION

Airway Occlusion Pressure

Maximal Inspiratory Airway Pressure

Breathing Pattern

Changes in End-Expiratory Lung Volume

RESPIRATORY MECHANICS

Elastance (Compliance)

Pressure-Volume Curves

Resistance

Intrinsic Positive End-Expiratory Pressure

Airway Pressure Profile

Flow-Volume Curves

Various devices are available for effective and noninvasive monitoring of the patient's gas exchange function, respiratory neuromuscular capacity, and respiratory mechanics. Such measurements are helpful in characterizing the pathophysiology of an underlying respiratory disorder, tracking the course of illness and the effects of treatment, minimizing the risk of complications, and determining the patient's readiness for the withdrawal of therapeutic interventions and support devices.

Advances in respiratory monitoring continue to occur in terms of technological improvements and in enhancing current understanding of the pathophysiology of respiratory failure.¹ It is estimated that 20% to 40% of patients in intensive care units (ICUs) are admitted solely for the purposes of monitoring and do not receive any treatment that is unique to the ICU.²

GAS EXCHANGE

The human eye is poor at recognizing hypoxemia.^{3,4} With the availability of pulse oximetry, episodic hypoxemia has been found to be more common than was previously suspected, with an incidence ranging from 20% to 82%.⁵ Patients experiencing hypoxemia have a threefold higher risk of death compared with patients who do not display desaturations.⁶ Whether earlier detection and treatment of episodic hypoxemia can affect patient outcome is not known.

PULSE OXIMETRY

Pulse oximeters determine oxygen (O_2) saturation by measuring light absorption of arterial blood at two specific wavelengths, 660 nm (red) and 940 nm (infrared).^{7,8} The ratio of absorbencies at these two wavelengths is calibrated empirically against direct measurements of arterial blood oxygen saturation (SaO_2), and the resulting calibration algorithm is used to generate the pulse oximeter's estimate of arterial saturation (SpO_2).⁹ In addition to the digital readout of O_2 saturation, most pulse oximeters display a plethysmographic waveform, which can help clinicians distinguish an artifactual signal from the true signal (Fig. 13.1).

ACCURACY

The accuracy of commercially available oximeters in critically ill patients has been validated in several studies.¹⁰ Compared with the measurement standard (multiwavelength oximeter), pulse oximeters have a mean difference (bias) of less than 1% and a standard deviation (precision) of less than 2% when SaO_2 is 90% or above.⁸ Although pulse oximetry is accurate in reflecting one-point measurements of SaO_2 , it does not reliably predict changes in SaO_2 . In 1085 simultaneous measurements of SaO_2 and SpO_2 in 41 ICU patients, changes in SaO_2 correlated moderately with changes in SpO_2 ($r = 0.6$), and the pulse oximeter tended to overestimate actual changes in SaO_2 .¹¹

The accuracy of pulse oximeters deteriorates when SaO_2 falls to 80% or less.¹² In critically ill patients, poor

Figure 13.1 Common pulsatile signals on a pulse oximeter. *Top tracing*, Normal signal showing the sharp waveform with a clear dicrotic notch. *Second tracing*, Pulsatile signal during low perfusion showing a typical sine wave. *Third tracing*, Pulsatile signal with superimposed noise artifact giving a jagged appearance. *Bottom tracing*, Pulsatile signal during motion artifact showing an erratic waveform. (From Jubran A: Pulse oximetry. In Tobin MJ (ed): Principles and Practice of Intensive Care Monitoring. New York, McGraw-Hill, 1998, pp 261-287.)

Box 13.1 Limitations of Pulse Oximetry

- Physiologic limitations
 - Shape of oxyhemoglobin dissociation curve
- Interference from substances
 - Dyshemoglobins: carboxyhemoglobin, methemoglobin
 - Dyes
 - Nail polish
 - Ambient light
 - Skin pigmentation
- Limitation in signal processing
 - Low-perfusion state
 - Motion artifact
 - False alarms
- Limitation in knowledge of the technique

agreement between the oximeter and a CO-oximeter was observed, with bias ranging from -12% to 18% ; and oximetry tended to systematically underestimate SaO_2 when it was less than 80% .¹³

LIMITATIONS

Oximeters have a number of limitations that may lead to inaccurate readings (Box 13.1). Pulse oximeters measure SaO_2 , which is physiologically related to arterial oxygen tension (PaO_2) according to the O_2 dissociation curve. Because the dissociation curve has a sigmoid shape, oximetry is relatively insensitive in detecting hypoxemia in patients with high baseline levels of PaO_2 .^{8,14}

Pulse oximeters use only two wavelengths of light; accordingly, they can discriminate only two substances, oxyhemoglobin and reduced hemoglobin. Elevated carboxyhemoglobin and methemoglobin levels can therefore cause inaccurate oximetry readings.¹⁵⁻¹⁸ Anemia does not appear to affect the accuracy of pulse oximetry.^{19,20}

Intravenous dyes such as methylene blue, indocyanine green, and indigo carmine can cause falsely low SpO_2 readings, an effect that persists for up to 20 minutes.²⁰ In critically ill patients requiring mechanical ventilation, nail polish—blue, white, purple, and black—has been shown not to affect the accuracy of SpO_2 readings;²¹ acrylic nails, however, may interfere with readings.²² Falsely low and falsely high SpO_2 readings occur with fluorescent and xenon arc surgical lamps.²³

Skin pigmentation can affect the accuracy of pulse oximetry.^{24,25} In critically ill patients,¹² bias plus precision was greater in black patients, $3.3 \pm 2.7\%$, than in white patients, $2.2 \pm 1.8\%$; also, a bias greater than 4% occurred more frequently in black patients (27%) than in white patients (11%).

Low-perfusion states, such as low cardiac output, vasoconstriction, and hypothermia, may impair peripheral perfusion, making it difficult for a sensor to distinguish a true signal from background noise. In patients experiencing hypothermia and poor perfusion during cardiac surgery, only 2 of 20 oximeters (Criticare CSI 503, Datex Satlite, Helsinki, Finland) provided measurements within $\pm 4\%$ of the CO-oximeter value.²⁶ Measurements of SpO_2 with a Biox 3700 oximeter had an associated bias greater than $\pm 4\%$ in 37% of patients receiving vasoactive therapy.²⁷

Motion artifact is a frustrating problem, and it results in inaccurate readings and false alarms. Patient motion is a common reason for temporary or definitive abandonment of pulse oximetry in a particular patient. An innovative technological approach, termed *Masimo Signal Extraction Technology* (SET), was introduced to extract the true signal from artifact secondary to noise and low perfusion²⁸ (Fig. 13.2).

In 18 healthy volunteers, investigators compared the latest generation of pulse oximeters—Masimo SET (Irvine, CA), Nellcor OxismartXL (Pleasanton, CA), Philips Medical Systems FAST- SpO_2 (Andover, MA), Respironics Novamatrix MARS SpO_2 (Wallingford, CT), and Siemens Oxisure (Danvers, MA)—with an older model, Nellcor N-200, under conditions of low perfusion and motion.¹⁰ Of the five new-generation oximeters, Masimo SET and Nellcor OxismartXL outperformed the other three devices in reducing nuisance alarms and ensuring alarm reliability. These two oximeters also were found to have better protection against light interference than the other three devices.

Despite their popularity for continuous monitoring of O_2 saturation, pulse oximeters fail to provide valid data in a variety of settings.²⁹⁻³¹ In a prospective study in ICU patients, SpO_2 signals accounted for almost half of a total of 2525 false alarms.³² In 235 surgical ICU patients, a study revealed that false alarms from the pulse oximeter were secondary to low perfusion (21%), cardiac arrhythmias (9%), motion artifacts (8.4%), shivering (1.7%), and extubation (1.7%).³³

An underrecognized and worrisome problem with pulse oximetry is that many users have a limited understanding of how the oximeter functions and the implications of the measurements obtained. One survey revealed that 30% of physicians and 93% of nurses thought that the oximeter measured PaO_2 . Some clinicians did not recognize that SpO_2 values in the high 80s represent seriously low values of PaO_2 . Of special concern was the observation that some doctors and nurses were not especially worried about patients with

Figure 13.2 Pulse oximetry signals with motion artifact: *top panel*, recorded during nonrhythmic motion (i.e., gross arm motion); *lower panel*, recorded during parkinsonian tremor. *Red line* denotes Masimo Signal Extraction Technology (SET), aimed at minimizing spurious pulse oximetry readings due to motion artifact; *blue line* denotes conventional pulse oximetry. Spurious changes in measured oxygen saturation (SpO_2) less with Masimo SET than with conventional pulse oximetry. (From Dumas C, Wahr JA, Tremper KK: Clinical evaluation of a prototype motion artifact resistant pulse oximeter in the recovery room. *Anesth Analg* 1996;83:269-272.)

SpO_2 values as low as 80% (equivalent to PaO_2 less than 45 mm Hg)³⁴ (Fig. 13.3). Another audit demonstrated that fewer than 50% of nurses and physicians were able to identify that motion artifact and arrhythmias can affect the accuracy of pulse oximetry.³⁵

CLINICAL APPLICATIONS

With the introduction of pulse oximetry, hypoxemia (defined as an SpO_2 value less than 90%) is now detected more often in critically ill patients.³⁶ Changes in SpO_2 may not accurately reflect changes in PaO_2 . Accordingly, caution is required in clinical decision making in critically ill patients based solely on pulse oximetry. Although pulse oximetry is a suitable way of measuring arterial oxygenation, it does not assess ventilation. Indeed, measurements of SpO_2 have been shown to be inaccurate in assessing abnormal pulmonary gas exchange, defined as an elevated alveolar-arterial O_2 difference.⁵

Pulse oximetry can assist with titration of fractional inspired oxygen concentration (FIO_2) in ventilator-dependent patients, although the appropriate SpO_2 target depends on a patient's pigmentation.¹² The SpO_2 target value that predicts a satisfactory level of oxygenation is 92% in white patients and 95% in black patients (Fig. 13.4).

Figure 13.3 The lowest values for O_2 saturation measured by pulse oximetry (SpO_2) considered acceptable in a fit adult by a group of physicians and nurses. SpO_2 values less than 88% (equivalent to PaO_2 of less than 55 mm Hg) were considered acceptable by 27% of the respondents. The percentages represented by bars for each of the respondent groups add up to 100%. (Modified from Stoneham MD, Saville GM, Wilson IH: Knowledge about pulse oximetry among medical and nursing staff. *Lancet* 1994;344:1339-1342.)

Pulse oximetry has been evaluated as a means of screening for respiratory failure in patients with severe asthma.³⁷ Respiratory failure was unlikely in patients with SpO_2 greater than 92%. Of interest, this threshold value of 92% is the same target value that reliably predicted a satisfactory level of oxygenation during titration of FIO_2 in ventilator-dependent patients.¹²

The use of pulse oximetry compared with other vital signs in predicting hospital complications from pulmonary embolus has been investigated.³⁸ In 207 patients with documented pulmonary embolism, a room-air SpO_2 value obtained in the emergency department was the most important predictor of death: the mortality rate was 2% in patients with SpO_2 95% or greater versus 20% with SpO_2 less than 95%. When the threshold value was prospectively evaluated in 119 patients, in 10 of whom hospital complications developed, SpO_2 less than 95% had a sensitivity of 90%, specificity of 64%, and overall diagnostic accuracy of 67%. Although the number of patients with complications was low, these data suggest that pulse oximetry may be useful in predicting outcome in patients with pulmonary embolus.

Moller and associates³⁹ conducted the first prospective, randomized study of pulse oximetry on the outcome of anesthesia care in 20,802 surgical patients. Detection of hypoxemia (defined as an SpO_2 less than 90%) was 19-fold higher in the oximeter group than in the control group. Myocardial ischemia was more common in the control group than in the oximetry group, occurring in 26 and 12 patients, respectively. Pulse oximetry, however, did not decrease the rate of postoperative complications or mortality.

The lack of proven efficacy of pulse oximetry in the study of Moller and associates³⁹ was related to the sample size. These investigators concluded that it would take at least 500,000 patients to show a reduction in a rare event such as myocardial infarction and 1.9 million patients to show a reduction in anesthesia-related deaths. When

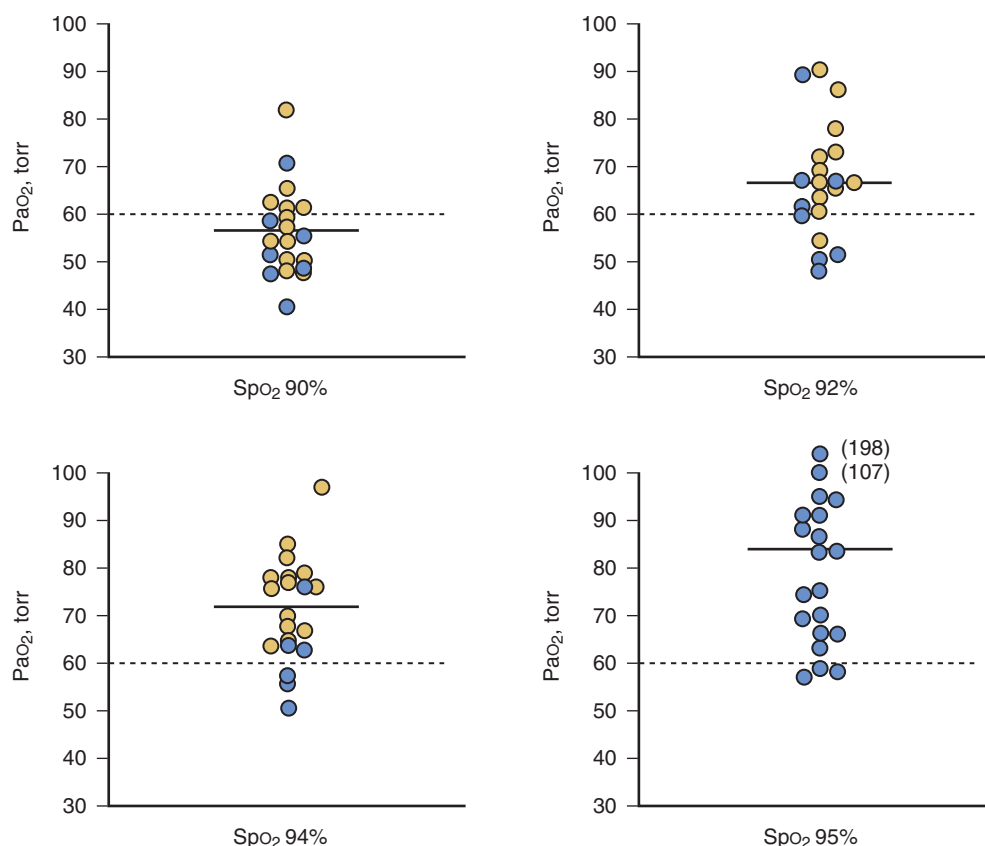

Figure 13.4 Arterial oxygen tension (PaO_2) values at pulse oximetry O_2 saturation (SpO_2) values of 90%, 92%, 94%, and 95%. The inspired O_2 concentration (FiO_2) was adjusted to achieve a particular steady-state SpO_2 value in a group of 54 critically ill patients. The solid horizontal line represents the mean PaO_2 value obtained at each SpO_2 target. The orange and blue circles represent values obtained in white and black patients, respectively. In white patients, an SpO_2 target of 92% resulted in a satisfactory level of oxygenation, whereas a higher SpO_2 target, 95%, was required in black patients. (Modified from Jubran A, Tobin MJ: Reliability of pulse oximetry in titrating supplemental oxygen therapy in ventilator-dependent patients. *Chest* 1990;97:1420-1425.)

anesthesiologists in the study were surveyed,⁴⁰ 80% of them reported feeling more secure when they used a pulse oximeter. Of 104 anesthesiologists, 19 believed that the pulse oximeter helped them avoid serious complications (such as esophageal intubation, tracheal tube disconnection or displacement, anesthesia machine failure, and respiratory problems immediately after extubation). It is this mindset that has established pulse oximetry as an essential component of the standard of care despite a failure to achieve a level of proven efficacy with a p value of less than 0.05. The lack of concurrence between randomized trial proof of efficacy of pulse oximetry and its requirement as part of the standard of care has major ramifications for all monitoring techniques.¹

COST EFFECTIVENESS

Studies evaluating the cost effectiveness of pulse oximetry have reported that fewer arterial blood gas (ABG) samples were obtained if SpO_2 data were available to the caregivers.⁴¹⁻⁴³ The effect of implementing pulse oximetry in an ICU without any specific plan for its appropriate use was examined in 148 patients before the implementation of oximetry and 141 patients after its implementation.⁴⁴ The number of ABG samples decreased from 7.2 to 6.4 per patient per day—a reduction of only 10.3%, compared with average

reductions of 39% in the previous studies.⁵ This suggests that without explicit guidelines, the pulse oximeter was used in addition to, rather than instead of, blood gas sampling.

Pulse oximetry probably constitutes one of the most important advances in respiratory monitoring. The major challenge facing pulse oximetry is whether this technology can be incorporated effectively into diagnostic and management algorithms that improve the efficiency of clinical management in the ICU.

TRANSCUTANEOUS BLOOD GAS MONITORING

Transcutaneous measurements of O_2 tension (PtcO_2) are made by placing a heated Clark polarographic electrode directly on the skin and measuring the O_2 that diffuses from the blood to the skin.⁴⁵ This technique more commonly is used by neonatologists because neonatal skin is thin, so PtcO_2 values approximate PaO_2 values. In a multicenter study including 251 patients of various ages (range, 4 weeks to 60 years), the $\text{PtcO}_2/\text{PaO}_2$ ratio was 1.05 in neonates and 0.93 in older patients when PaO_2 was less than 80 mm Hg. This ratio, however, decreased to 0.88 in neonates and 0.74 in older patients when the PaO_2 was greater than 80 mm Hg.⁴⁶ During low-perfusion states, PtcO_2 measurements do not reflect changes in PaO_2 . In critically ill patients,

the P_{tCO_2}/P_{aO_2} ratio decreased from 0.79 ± 0.12^5 when the cardiac index was greater than 2.2 L/minute/m^2 to 0.12 ± 0.12 when the cardiac index was less than 1.5 L/minute/m^2 .⁴⁷

Transcutaneous monitoring of the partial pressure of carbon dioxide (P_{tCO_2}) can be performed using a modified Severinghaus electrode. The underlying skin is heated to 44°C to enhance CO_2 diffusion through the skin. Heating also increases the local production of CO_2 , with the result that transcutaneous P_{CO_2} values usually are higher than arterial P_{CO_2} (P_{aCO_2}) values.⁴⁷ Because of greater diffusibility of CO_2 compared with O_2 through the skin, the correlation of P_{tCO_2} with P_{aCO_2} usually is good: $r = 0.93$.⁴⁶

The accuracy of P_{tCO_2} as a surrogate measure for P_{aCO_2} was evaluated in 50 critically ill patients in a medical ICU.⁴⁸ Of the 189 paired measures of P_{CO_2} obtained, 21 were excluded from analysis because of profound skin vasoconstriction. Of the available 168 measurements, mean difference between P_{aCO_2} and P_{tCO_2} was $-0.2 \pm 4.6 \text{ mm Hg}$; correlation between two measurements was 0.92. A strong correlation was observed between changes in P_{aCO_2} and P_{tCO_2} ($r^2 = 0.78$) (Fig. 13.5). These data suggest that transcutaneous P_{CO_2} may be reliable in monitoring changes in P_{aCO_2} , provided that no major vasoconstriction is present.

CAPNOGRAPHY

The carbon dioxide concentration at the end of a tidal breath—end-tidal CO_2 —can be employed as a continuous, indirect measure of P_{aCO_2} . In intubated patients with respiratory failure, correlation between end-tidal CO_2 and P_{aCO_2} was good ($r = 0.78$).⁴⁹ The correlation between changes in end-tidal CO_2 and changes in P_{aCO_2} from baseline, however, was considerably weaker ($r = 0.58$). Change in end-tidal CO_2 incorrectly indicated the direction of change in P_{aCO_2} in 43% of patients being weaned from mechanical ventilation after cardiac surgery.⁵⁰

Capnometry commonly is used in detecting esophageal intubation⁵¹⁻⁵³ (Fig. 13.6). When the trachea of a patient with an intact pulmonary circulation is intubated, end-tidal CO_2 is recorded. When, however, the endotracheal tube is erroneously placed in the esophagus, end-tidal CO_2 will

be zero. Monitoring of end-tidal CO_2 has been compared with three other methods—auscultation, negative-pressure testing using a self-inflating bulb, and transillumination—for verifying tracheal tube placement.⁵⁴ Monitoring of end-tidal CO_2 was found to be the most reliable.

RESPIRATORY NEUROMUSCULAR FUNCTION

AIRWAY OCCLUSION PRESSURE

Measuring airway pressure 0.1 second after initiation of an inspiratory effort against airway occlusion ($P_{0.1}$) provides a

Figure 13.5 Change in transcutaneous P_{CO_2} (P_{tCO_2}) versus change in arterial P_{CO_2} (P_{aCO_2}) in 40 samples. The solid line represents the linear regression equation ($R^2 = 0.78$); broken lines represent P_{tCO_2} values at 0, +5, and -5 mm Hg. Note that a mismatch between changes in P_{tCO_2} and P_{aCO_2} (transcutaneous changes were positive although arterial changes were negative, or vice versa) occurred in 8 of the 40 values (22%). (Modified from Rodriguez P, Lellouche F, Aboab J, et al: Transcutaneous arterial carbon dioxide pressure monitoring in critically ill adult patients. *Intensive Care Med* 2006;32: 309-312.)

Figure 13.6 End-tidal CO_2 tracing and esophageal intubation. *Upper panel:* End-tidal CO_2 tracing in a patient in whom an endotracheal tube was inserted correctly in the trachea. During inhalation, end-tidal CO_2 is 0 mm Hg. During exhalation, the CO_2 tracing rises steeply, attains a near plateau, and then quickly returns to the baseline. *Lower panel:* End-tidal CO_2 tracing in a patient in whom an endotracheal tube was erroneously inserted in the esophagus. The expected shape of the CO_2 tracing has been replaced by small transient rises in the CO_2 tracing, which progressively decrease with each squeeze of the Ambu bag.

measure of respiratory drive. In ventilator-dependent patients, $P_{0.1}$ has been shown to correlate significantly with the work of breathing during pressure-support ventilation ($r = 0.87$).⁵⁵ By taking advantage of the decrease in airway pressure to open the demand valve during triggering, investigators have demonstrated that commercially available ventilators can measure $P_{0.1}$ accurately.⁵⁶ Several studies⁵⁶⁻⁵⁸ have indicated that an elevated $P_{0.1}$ predicted weaning failure, but the threshold separating success from failure differed among the studies.⁵⁹

MAXIMAL INSPIRATORY AIRWAY PRESSURE

Maximum inspiratory pressure (Pimax), a global measure of inspiratory muscle strength, is measured using a one-way valve that allows exhalation but prevents inhalation.^{60,61} Pimax is one of the standard measurements employed to determine a need for the continuation of mechanical ventilation. Values that are more negative than -30 cm H₂O are considered to predict weaning success; values that are less negative than -20 cm H₂O are predictive of weaning failure. These criteria, however, frequently are falsely positive and falsely negative.⁶²

BREATHING PATTERN

Rapid shallow breathing is a common respiratory pattern in patients who fail a trial of weaning from mechanical ventilation,⁶³ and this can be quantitated in terms of the frequency-to-tidal volume ratio (f/V_T). The higher the f/V_T , the more pronounced the rapid, shallow breathing and the greater the likelihood of unsuccessful weaning. An f/V_T above 100 breaths per minute per liter suggests that a trial of weaning is unlikely to be successful.⁶² When prospectively evaluated, f/V_T was found to be superior to nine other weaning predictors: sensitivity was 0.97, specificity 0.64, positive predictive value 0.78, and negative predictive value 0.95.⁶⁰

The usefulness of f/V_T in predicting weaning outcome was challenged. Using a meta-analysis, an American College of Chest Physicians (ACCP) Task Force concluded that f/V_T was unreliable.^{64,65} In their evaluation of published reports on f/V_T , the Task Force ignored the important influence of pretest probability on the interpretation of test results. The implications of pretest probability are greater for weaning than for many clinical situations because weaning involves a sequence of three diagnostic tests: measurement of predictors, followed by a weaning trial, followed by an extubation trial. The undertaking of three diagnostic tests in a sequential manner poses an enormous risk for the occurrence of test referral and spectrum bias. The introductions of such biases will, in turn, increase the pretest probability.^{66,67} Indeed, the mean pretest probability of weaning success was 75% in the studies included in the meta-analysis. When data from studies included in the Task Force meta-analysis were entered into a bayesian model with pretest probability as the operating point, the observed post-test probabilities were closely correlated with the values predicted by the original study on f/V_T : $r = 0.86$ for positive predictive value and $r = 0.82$ for negative predictive value.⁶⁸

It has been suggested that measurements of f/V_T at 30 minutes into a weaning trial more accurately predict outcome than measurements in the first minute.^{69,70}

Although it is true that including data for the first 30 seconds or so may be unrepresentative, this does not mean that it takes 30 minutes to establish a steady state.

Jubran and colleagues⁷⁰ studied the time required for f/V_T to reach a point of equilibration in 17 weaning failure and 14 weaning success patients. The median time (plus interquartile range) to reach +10% of the final value of f/V_T was 2 (1 to 2) minutes in both the weaning success and the weaning failure patients (Fig. 13.7). Within 2 minutes of the onset of the T-tube trial, 77% of the weaning failure patients and 73% of the weaning success patients had reached +10% of the final value of f/V_T . As indicated by these data, a reasonable strategy is to commence measurement of f/V_T at 60 seconds after removal of the ventilator and then continue the measurement for another 60 seconds.

Continuous recording of breathing pattern provides an important approach for assessing the ability of the respiratory controller to maintain or adjust its response over time.⁷¹ Simple measurements, such as coefficients of variation, indicate that healthy subjects display considerable variation in tidal volume and respiratory cycle time from one breath to the next.⁷² Signal analysis techniques reveal that this variability is composed of random and nonrandom fractions.⁷³⁻⁷⁸ The predominantly random character of the variability makes it possible for the respiratory system to engage in tasks other than gas exchange. A smaller fraction of variability is nonrandom; moreover, tidal volume and

Figure 13.7 Time-series plot of frequency-to-tidal volume ratio (f/V_T) during a T-tube trial of spontaneous breathing in a weaning failure patient. Black dots represent 1-minute averages. The solid line indicates the average value of f/V_T of the final minute of the trial. The dashed horizontal lines indicate +10% of the final minute values of f/V_T . The time taken to reach +10% of the final value of f/V_T was 2 minutes. (From Jubran A, Grant BJ, Laghi F, et al: Weaning prediction: Esophageal pressure monitoring complements readiness testing. *Am J Respir Crit Care Med* 2005;171:1252-1259.)

respiratory cycle time of one breath are significantly related to those of the preceding breath.^{73,74,76,77} When healthy subjects are faced with external chemical or mechanical loads, however, the random fraction decreases significantly.^{74,76,77} This decrease in random variability may lessen the freedom of the respiratory system to undertake behavioral tasks.^{76,77,79}

Using autocorrelation analysis and fast-Fourier transformation, Brack and associates⁸⁰ showed that patients with restrictive lung disease display a marked decrease in breath-to-breath variability of breathing. The random fraction of variability was approximately $\frac{1}{27}$ of that found in healthy subjects, and the nonrandom correlated fraction was as much as three times higher in the patients. Slight variations from the average resting tidal volume caused large increases in dyspnea in the patients, but not in the healthy subjects⁸⁰ (Fig. 13.8). In patients undergoing a weaning trial, Wysocki and coworkers⁸¹ noted a higher gross variability of breathing

(quantitated in terms of coefficient of variation) in patients who were successfully weaned than in patients who failed the trial. These data suggest that an increase in the ability to vary breathing may be associated with a favorable weaning outcome.⁸²

CHANGES IN END-EXPIRATORY LUNG VOLUME

Alterations in the end-expiratory level of signal from an inductive plethysmograph can provide a measurement of the change in functional residual capacity provided that motion artifact is absent^{83,84} (Fig. 13.9). Inductive plethysmography has been used to estimate a patient's level of auto-PEEP (positive end-expiratory pressure).⁴⁹ By noting the level of external PEEP at which end-expiratory lung volume increased, a close estimate of the patient's original level of auto-PEEP can be obtained. An attractive feature of this technique is that it does not disturb expiration, unlike the occlusive technique, in which foreshortening of expiratory time is unavoidable.⁸⁵

Figure 13.8 The relationship between variation in tidal volume and dyspnea (Borg score) in patients with restrictive lung disease and in control subjects. Dyspnea scores were higher in the patients than in the control subjects ($P < 0.01$, ANOVA); dyspnea varied with tracked volume in the patients ($P < 0.05$, ANOVA) but not in the control group. The regression between dyspnea and tidal volume was parabolic in the patients ($y = 10.3 - 0.12x + 0.0005x^2$; $P < 0.0001$), but not in the control subjects ($y = 2.76 - 0.02x + 0.00008x^2$; $P = 0.5$). Bars represent \pm SEM. ANOVA, analysis of variance; SEM, standard error of the mean. (From Brack T, Jubran A, Tobin MJ: Dyspnea and decreased variability of breathing in patients with restrictive lung disease. *Am J Respir Crit Care Med* 2002;165:1260-1264).

RESPIRATORY MECHANICS

Measurements of respiratory mechanics in a relaxed ventilator-dependent patient can be obtained using the technique of rapid airway occlusion during constant-flow inflation.⁸⁶ Rapid airway occlusion at the end of a passive inflation produces an immediate drop in both airway pressure (Paw) and transpulmonary pressure (PL) from a peak value (Ppeak) to a lower initial value (Pinit), followed by a gradual decrease until a plateau (Pplat) is achieved after 3 to 5 seconds^{87,88} (Fig. 13.10). Pplat on the Paw, PL, and Pes tracings represents the static end-inspiratory recoil pressure of the total respiratory system, lung, and chest wall, respectively.

ELASTANCE (COMPLIANCE)

The end-inspiratory airway occlusion method is used clinically to measure the static compliance, or its reciprocal, elastance, of the respiratory system (Est,rs) according to the following equation⁸⁹:

Figure 13.9 Changes in lung volume measured by inductive plethysmography (top tracing), raw electromyographic signal of scalene muscle activity (EMG) (middle tracing), and moving time average (bottom, integrated signal) during three consecutive cycles of Cheyne-Stokes breathing in a representative patient. Note the repeated increases in end-expiratory lung volume with each hyperpnea. (From Brack T, Jubran A, Laghi F, Tobin MJ: Fluctuations in end-expiratory lung volume during Cheyne-Stokes respiration. *Am J Respir Crit Care Med* 2005;171:1408-1413.)

Figure 13.10 Flow (inspiration upward), airway pressure (Paw), transpulmonary pressure (PL), and esophageal pressure (Pes) tracings in a representative patient during passive ventilation. An end-inspiratory occlusion produced a rapid decline in both Paw and PL from a peak value (P_{peak}) to a lower initial pressure (P_{init}), followed by gradual decrease to a plateau pressure (P_{plat}). P_{plat} on the Paw, PL, and Pes tracings represents the static end-inspiratory recoil pressures of the total respiratory system, lung, and chest wall, respectively. Using this technique, total resistance can be partitioned into ohmic airway resistance and tissue resistance, which reflects the viscoelastic properties (stress relaxation) and time-constant inhomogeneities within the respiratory tissues. (Modified from Jubran A, Tobin MJ: Passive mechanics of lung and chest wall in patients who failed and succeeded in trials of weaning. *Am J Respir Crit Care Med* 1997;155:916-921.)

$$\text{Est, rs} = P_{\text{plat}} - \text{PEEP}_{\text{tot}} / V_T$$

where P_{plat} is plateau pressure obtained after occlusion of the airway, PEEP_{tot} is the sum of external and intrinsic PEEPs if present, and V_T is tidal volume (see Fig. 13.10).

Mechanical ventilation in itself can produce or aggravate lung injury in patients with acute respiratory distress syndrome (ARDS).⁹⁰⁻⁹² Injury may be decreased by minimizing alveolar overdistention. To avoid lung injury, ideally the alveolar volume should be monitored, but that is not possible. Alveolar volume is reflected by peak alveolar pressure, which can be assessed indirectly by measuring the plateau pressure during an end-inspiratory hold maneuver. It has been recommended that plateau pressure not exceed 32 cm H₂O.^{93,94}

A new era of ventilatory management began in 1990, when a report demonstrated that lowering tidal volume caused a 60% decrease in the expected mortality rate among patients with ARDS.⁹⁵ Subsequently, randomized trials were undertaken.⁹⁶⁻⁹⁹ In 861 patients, the ARDS Network investigators reported a 22% difference in mortality rates with use of a tidal volume of 6 mL/kg versus 12 mL/kg.¹⁰⁰ It is now generally accepted that the use of high tidal volumes in patients with ARDS is associated with high mortality rates.^{93,101} Whether the use of low tidal volumes implies a survival advantage is controversial.¹⁰¹⁻¹⁰³

PRESSURE-VOLUME CURVES

A pressure-volume curve of the respiratory system in a paralyzed patient can be constructed by measuring the airway pressure as the lungs are progressively inflated with a 1.5- to 2-L syringe. A lower inflection point and an upper inflection point may be seen on the pressure-volume curve.¹⁰⁴ The lower inflection point is thought to reflect the point at which small airways or alveoli reopen, corresponding to closing volume. In patients with acute lung injury, investigators have recommended that PEEP be set at a pressure slightly above the lower inflection point.¹⁰⁵

When an “open-lung approach,” consisting of use of a lower tidal volume (less than 6 mL/kg) with PEEP individually titrated to be consistently above the inflection point on the pressure-volume curve, was compared with a conventional approach, consisting of use of tidal volume of 12 mL/kg and a low PEEP level, the mortality rate was significantly reduced in the group managed with the new approach.^{96,106}

A National Institutes of Health (NIH)-sponsored trial of high versus low PEEP, however, failed to demonstrate a significant survival advantage for patients randomized to the high PEEP group.¹⁰⁷ Several methodologic considerations cast doubt on the conclusions of the investigators.¹⁰⁸ First, baseline characteristics of the two groups were not balanced; the low PEEP group patients had higher $\text{PaO}_2/\text{FiO}_2$ ratios and were younger than patients in the high PEEP group. Second, PEEP-induced recruitment was estimated by improvement in oxygenation. It is well known that changes in oxygenation depend not only on recruitment but also on cardiac output.¹⁰⁹ Thus, oxygenation may have improved without any lung recruitment. Third, recruitment potential was not stratified, so that patients who were not likely to benefit were assigned to both groups.¹¹⁰

The importance of individualizing PEEP in ventilator management in patients with ARDS was confirmed in a Spanish trial. One group of patients was randomized to a treatment group in which PEEP was titrated to 2 cm H₂O above the lower inflection point. The mortality rate was lower in these patients than in control group patients who did not receive customized titration of PEEP.¹¹¹

RESISTANCE

Airway resistance can be measured in ventilator-dependent patients using the technique of rapid airway occlusion during constant-flow inflation^{86,87,89,112} (see Fig. 13.10).

Measurements of airway resistance are helpful in assessing the response of patients to bronchodilator therapy. In a

Figure 13.11 Recordings of flow, airway pressure (Paw), and esophageal pressure (Pes) in a patient receiving controlled mechanical ventilation. After the third breath, the airway was occluded at end-expiration using the end-expiratory hold function on the ventilator. During the period of zero flow, pressure in the alveoli and in the ventilator circuit equilibrates, and the plateau pressure reflects auto- or intrinsic positive end-expiratory pressure (PEEPi), indicated by the arrow.

study in ventilator-dependent patients with chronic obstructive pulmonary disease (COPD), a significant decrease in airway resistance occurred after giving 4 puffs, with no further effect after the addition of 8 and 16 puffs (cumulative doses of 12 and 28 puffs).^{113,114}

INTRINSIC POSITIVE END-EXPIRATORY PRESSURE

The static recoil pressure of the respiratory system at end-expiration may be elevated in patients receiving mechanical ventilation.⁸⁹ This positive recoil pressure, or intrinsic PEEP (static PEEPi), can be quantified in relaxed patients using an end-expiratory hold maneuver on a mechanical ventilator immediately before the onset of the next breath^{11,115} (Fig. 13.11), or as a change in Paw required to reduce expiratory flow to zero and initiate lung inflation by the ventilator (dynamic PEEPi). In patients with COPD, dynamic PEEPi is lower than static PEEPi; this discrepancy is attributed to the presence of time-constant inequalities.^{116,117}

PEEPi poses a significant inspiratory threshold load that has to be fully counterbalanced by increasing inspiratory muscle effort in order to generate a negative pressure in the central airway and trigger the ventilator. Thus, PEEPi adds to the triggering pressure such that the total inspiratory effort needed to trigger the ventilator is the set trigger sensitivity plus the level of PEEPi. This is one of the factors that may account for the not infrequent observation of a patient who is unable to trigger a ventilator despite obvious respiratory effort¹¹⁸⁻¹²³ (Fig. 13.12).

In a study of ventilator-dependent patients, Leung and colleagues¹²⁰ reported that ineffective triggering occurred with all assisted modes of mechanical ventilation. The ineffective or wasted efforts were significantly related to resistance ($r = 0.85$), elastance ($r = -0.61$), and static PEEPi ($r = 0.77$). A decrease in the magnitude of inspiratory effort at a given level of assistance was not the cause—indeed, effort was 38% higher during nontriggering attempts than during the triggering phase of attempts that successfully opened

Figure 13.12 Recordings of tidal volume, flow, airway pressure (Paw), and esophageal pressure (Pes) in a patient with chronic obstructive pulmonary disease receiving pressure support ventilation. Approximately half of the patient's inspiratory efforts do not succeed in triggering the ventilator. Triggering occurred only when the patient generated a Pes less than 8 cm H₂O (indicated by the dashed line), which was equal in magnitude to the opposing elastic recoil pressure. (From Tobin MJ, Jubran A: Pathophysiology of failure to wean from mechanical ventilation. *Schweiz Med Wochenschr* 1994;124: 2139-2145.)

the inspiratory valve. Significant differences, however, were observed in the breaths before the triggering and nontriggering attempts. Breaths before nontriggering attempts were associated with shorter respiratory cycle time and expiratory time and higher static PEEPi compared with the

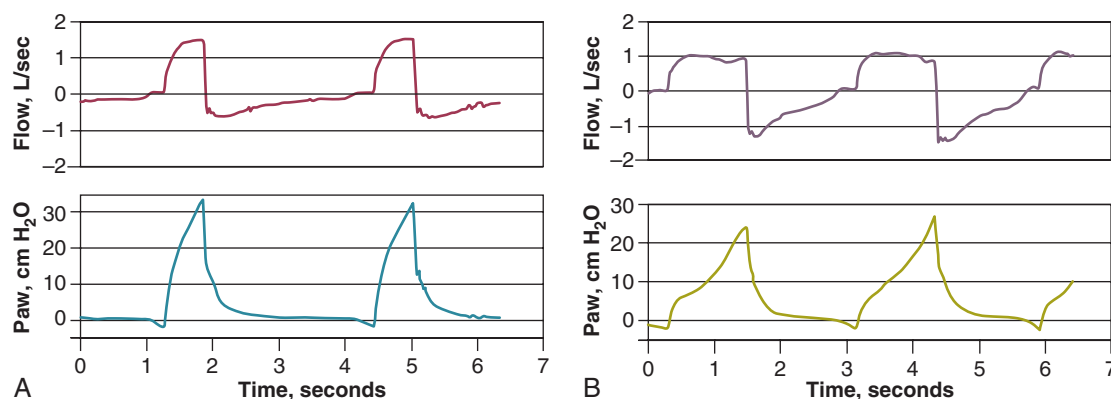

Figure 13.13 Flow and airway pressure (Paw) during assist-control ventilation at different flow rates: 60 L/minute (**A**) and 30 L/minute (**B**). **A**, The small negative phase coupled with the smooth rise and convex appearance of the Paw waveform indicates that the patient is making a slight inspiratory effort to breathe. **B**, The more pronounced negative phase together with excessive scalloping of the Paw waveform indicates that the patient is making a strenuous effort to breathe as a result of the inadequate flow setting. (From Jubran A, Tobin MJ: Monitoring during mechanical ventilation. In Tobin MJ (ed): Principles and Practice of Mechanical Ventilation. New York, McGraw-Hill, 2006, p 1051.)

breaths before triggered attempts. These findings suggest that ineffective triggering resulted not from a decrease in the magnitude of effort but rather from inspiratory efforts that were premature and insufficient to overcome the elevated elastic recoil pressure associated with dynamic hyperinflation.

AIRWAY PRESSURE PROFILE

A continuous recording of airway pressure provides helpful information about the amount of respiratory work being performed by a patient receiving ventilator assistance. Ideally the waveform should show a smooth rise with a convex appearance during inspiration.^{1,124} By contrast, a prolonged negative phase with excessive scalloping of the tracing reflects increased inspiratory effort; this pattern indicates unsatisfactory sensitivity and inappropriate flow settings (Fig. 13.13). A “bump” on the airway pressure tracing observed while the ventilator is still pumping gas in the patient may reflect recruitment of expiratory muscles (Fig. 13.14).

Use of a flow setting that does not meet a patient’s ventilatory demands will cause inspiratory effort to increase. Sometimes the flow is increased to shorten the inspiratory time and increase the expiratory time. An increase in flow, however, can cause immediate and persistent tachypnea; if this happens, the resulting decrease in expiratory time may lead to increased PEEPi.^{125,126} In general, however, an increase in inspiratory flow does not lead to an increase in PEEPi¹²⁶ (Fig. 13.15).

FLOW-VOLUME CURVES

Flow-volume curves may be helpful in indicating a need for endotracheal suctioning. In 50 intubated patients, Jubran and Tobin¹²⁷ found that the presence of a sawtooth pattern strongly suggested the presence of secretions (positive predictive value, 94%), and the absence of this pattern suggested that secretions are unlikely to be present (negative predictive value, 77%) (Fig. 13.16). Clinical examination had much higher false-positive and false-negative rates (42%

Figure 13.14 Recordings of flow (top) and airway pressure (Paw; middle) and transversus abdominis electromyogram (EMG; bottom) in a critically ill patient with chronic obstructive pulmonary disease receiving pressure support of 20 cm H₂O. The onset of expiratory muscle activity (vertical dotted line) occurred when mechanical inflation was only partly completed. (From Parthasarathy S, Jubran A, Tobin MJ: Cycling of inspiratory and expiratory muscle groups with the ventilator in airflow limitation. Am J Respir Crit Care Med 1998;158: 1471-1478.)

and 43%, respectively) than the flow-volume curves (12% and 14%, respectively). The usefulness of a sawtooth pattern for detecting secretions was confirmed by Guglielminotti and colleagues¹²⁸ in a study of 62 patients who were receiving pressure support or assist-control ventilation.

Figure 13.15 Continuous recordings of flow, esophageal pressure (Pes), and the sum of rib cage and abdominal motion in a patient with chronic obstructive pulmonary disease receiving assist-control ventilation at a constant tidal volume. As flow increased from 30 L/minute to 60 and 90 L/minute (from right to left), frequency increased (from 18 breaths per minute to 23 and 26 breaths per minute, respectively), PEEP_i decreased (from 15.6 cm H₂O to 14.4 and 13.3 cm H₂O, respectively), and end-expiratory lung volume also fell. Increases in flow from 30 L/minute to 60 and 90 L/minute also led to decreases in the swings in Pes from 21.5 cm H₂O to 19.5 and 16.8 cm H₂O, respectively. a.u., arbitrary units; PEEP_i, intrinsic positive end-expiratory pressure. (From Laghi F, Segal J, Choe WK, Tobin MJ: Effect of imposed inflation time on respiratory frequency and hyperinflation in patients with chronic obstructive pulmonary disease. *Am J Respir Crit Care Med* 2001;163:1365-1370.)

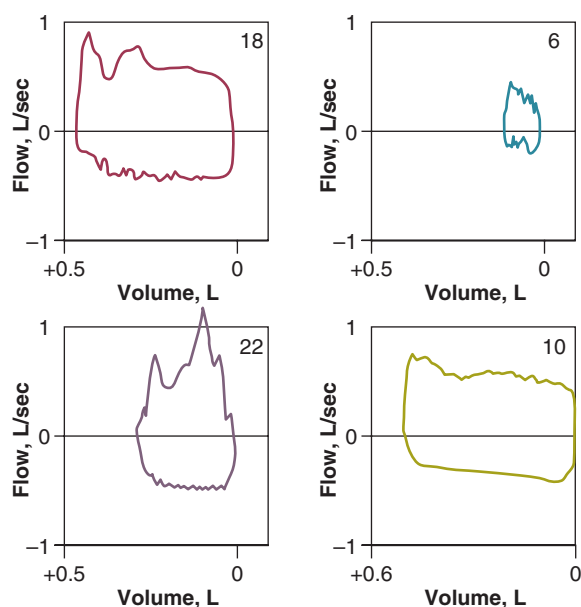

Figure 13.16 Flow-volume curves obtained in four patients with secretions. Note the presence of a sawtooth pattern on both the inspiratory and expiratory flow-volume curves. (The numbers to the upper right in each grid are the original patient numbers.) (From Jubran A, Tobin MJ: Use of flow-volume curves in detecting secretions in ventilator-dependent patients. *Am J Respir Crit Care Med* 1994;150:766-769.)

KEY POINTS

- Roughly 20% to 40% of patients in an ICU are admitted mainly for the purpose of monitoring.
- Pulse oximetry can accurately measure oxygen saturation at levels of 90% or above; its accuracy deteriorates when the saturation falls to 80% or less.
- Inaccurate readings from pulse oximetry can occur as a result of interference from substances or from problems in signal processing.
- Hypoxemia is detected more frequently in patients monitored with pulse oximetry than in patients in whom this modality is not used.
- Transcutaneous monitoring of PCO₂ may be reliable in monitoring changes in arterial PCO₂ in the absence of major vasoconstriction.
- Measuring airway pressure at 0.1 second after initiating an inspiratory effort against an occluded airway is closely associated with increased work of breathing during mechanical ventilation.
- One-time measurements of breathing pattern (frequency and tidal volume) are helpful in predicting weaning outcome; continuous measurements of breathing pattern can provide information about the function of the respiratory controller.
- Measurements of respiratory mechanics in a ventilator-dependent patient can be easily performed at the bedside using the rapid airway occlusion technique.
- Continuous recordings of airway pressure can provide useful information about the respiratory work performed by a patient receiving mechanical ventilation.
- Flow-volume curves may be helpful in indicating a need for endotracheal suctioning.

Percutaneous Dilational Tracheostomy Versus

Surgical Tracheostomy

HISTORY

Most medications, devices, and surgical techniques employed in today's intensive care unit (ICU) have resulted from twentieth century medical advances. However, one of the most common surgical procedures, tracheostomy, has been described for nearly 6000 years. The terms *tracheostomy* and *tracheotomy* are derived from the Greek words *tracheia arteria*, translated "rough artery," and refer to the trachea being the vital conduit of air.¹ Tracheostomy means permanent opening (*stoma*, Greek for "mouth"), to be distinguished from the temporary nature of a tracheotomy (*tome*, "to cut"). Today the terms are used interchangeably for any artificial airway created in the trachea, with tracheostomy used more commonly.

McClelland divides the history of the tracheostomy into five periods beginning with "The Period of Legend" (2000 BCE to 1546 CE).² The first written reference to tracheostomy is in the sacred book of Hindu medicine, the *Rig Veda*, dated between 2000 BCE and 1000 BCE, and describes "the bountiful one, who without a ligature, can cause the windpipe to reunite when the cervical cartilages are cut across."^{3,4} The earliest depictions of a tracheostomy being performed date back to about 3600 BCE and show two Egyptian kings undergoing a tracheostomy.^{5,6} Homer referred to tracheostomy as a way of relieving choking persons by cutting open the trachea, and Alexander the Great is described to have used the point of his sword to open the trachea of one of his soldiers who was choking while eating.² The next successful tracheostomy was performed in the second century CE by Antyllus as documented 400 years later by Paul of Aegina, who wrote that the use of tracheostomy was encouraged in cases of upper airway obstruction and provided a technical description of the operation.⁷ Mention of tracheostomy can be found in the Roman and Arabic literature,

although during the Dark Ages of medicine and science the technique of tracheostomy (and virtually all other surgeries) was forgotten for nearly 1000 years.^{6,8}

The second period, "The Period of Fear" (1536 to 1833),² starts with the Renaissance, when European physicians experimented with tracheostomy for trauma, aspirated foreign bodies, drowning, and Ludwig's angina. Fabricius of Aquapendente tells us that the timidity at that time was due partly to "lack of knowledge of anatomy, partly to fear of a loss of reputation, should the patient die after the operation." In his day, tracheostomy was known as the "scandal of surgery." About the same time, in 1546, the first definite account of a successful tracheostomy was recorded by Antonius Brasavola, who told of "opening the windpipe and saving the life of a patient near death from angina and an abscess which was obstructing the canalis pulmonis."^{1,8} Over the next 2 centuries, opposition to tracheostomy diminished because of the interest in anatomy and autopsy, as evidenced by the drawings and writings of Leonardo da Vinci, Julius Casserius, and others.^{6,9-11}

The clinical importance of tracheostomy became evident during sporadic diphtheria epidemics, and multiple publications of successful tracheostomies can be found in many European countries after 1620.⁸ In 1730, Scottish surgeon George Martine treated upper airway obstruction resulting from diphtheria with tracheostomy. He also recommended the use of an inner cannula for ease of care and recognized that tracheal wounds heal spontaneously without the need for surgical repair.^{8,12} In America, fear of tracheostomy was still quite prevalent, as evidenced in the well-known controversy surrounding the death of George Washington in 1799, when bloodletting won over relieving an epiglottitis-related upper airway obstruction with a tracheostomy.^{6,13} Until 1825, during these first several thousand years in the history of tracheostomy, only 28 tracheostomies are verifiable.

After Napoleon Bonaparte's nephew died of diphtheria in 1807, a grand prize was offered for new insights into this disease and its treatment. This heralded the "Period of Drama," which lasted from 1833 to 1931. Based on subsequent research, especially by Bretonneau and his pupil Trousseau, tracheostomy became a relatively established procedure, particularly for croup and diphtheria. Before Bretonneau, tracheostomy had been known under many different names, including bronchotomy, laryngotomy, pharyngotomy, sectio epiglottis, scisio cannae, and incisio cannae pulmonis. In 1718 Heister had introduced the term *tracheotomy* and recommended that all other terms be discarded, but it was not until Bretonneau used this term in a paper describing a successful operation in 1825 for diphtheria that it gained widespread acceptance.^{8,14} Trousseau described a series of 200 French children, most dying of diphtheria, in whom he reduced mortality rate from nearly 100% to 75% with tracheostomy.¹⁵ American surgeon Thomas Shastid published an account of performing tracheostomies on children in the 1890s in a small Illinois town during a diphtheria epidemic.^{16,17}

In the mid-1800s, Snow and Trendelenburg advocated tracheostomy for administration of inhaled anesthetics,^{3,18} but endotracheal intubation, performed by MacEwan in 1878¹⁹ and O'Dwyer in 1880,²⁰ and popularized by Bartholomay and Dufor in 1907 and Kelly in 1912, soon replaced tracheostomy as the route for delivering general anesthesia.^{3,21} This put the performance of tracheostomy squarely in the hands of surgeons experienced in upper airway problems, most notably Chevalier Jackson, whose name became virtually synonymous with tracheostomy. In his hands, the rate of mortality attributable to tracheostomy decreased from 25% to less than 5%.²²

The fourth period, the "Period of Enthusiasm" (1932 to 1965), was heralded by a revolutionary shift in the indications for the procedure and major advances in the technique. During this period the main sentiment was "if you think of tracheostomy, do it," without consideration of possible adverse outcomes. Up to then the main indication for tracheostomy was upper airway obstruction, mostly caused by severe croup and diphtheria, which practically disappeared as a result of the development of antibiotics and immunization. In the 1950s, with the poliomyelitis epidemic in Europe and North America, the need for positive-pressure ventilation (PPV) and tracheobronchial suctioning created new indications for tracheostomy.²³ At present, these are still the major indications for tracheostomy in the ICU, and they caused the number of tracheostomies performed at Massachusetts General Hospital to increase from fewer than 10 in 1947 to more than 150 in 1959. Before 1958, not a single tracheostomy was performed there for the sole purpose of providing PPV.²⁴

In the mid-1960s the last period in the history of tracheostomy began, the "Period of Rationalization." With the coming of age of the use of the endotracheal tube (ET) even for prolonged ventilatory support, a discussion of the advantages and disadvantages of both methods has emerged and is ongoing, especially with the development of percutaneous tracheostomy (PT).

The exponential increase in tracheostomy in the 1950s and 1960s revived older controversies. In 1921, Chevalier Jackson discussed proper technique and complications.²⁵

He condemned the use of high tracheostomy, believing it caused laryngeal stenosis. For 50 years, this was the prevailing wisdom of neck surgery and airway maintenance. Jackson drew his conclusions, however, primarily from unsterile emergency tracheostomies performed by inexpert practitioners.²⁵ Laryngeal stenosis probably resulted from factors other than the site of incision, especially when performed with preexistent laryngeal disease.^{26,27} Jackson's reputation made surgeons reluctant to perform high tracheostomies until the advent of cardiac surgery made them necessary to avoid contaminating median sternotomy incisions. In 1976, two cardiac surgeons, Brantigan and Grow, published the first large series of high tracheostomies and found few complications.²⁸ Acceptance of high tracheostomy permitted reintroduction of PT; a technique described 20 years earlier.

As previously described, when ICUs were developed, tracheostomy became one of the most frequently performed procedures in critically ill patients.²⁹ This created a need for a safe, cost-effective bedside procedure that would eliminate the necessity for transport of the patient from the ICU to the operating room, with its attendant risks, which are discussed subsequently.

In 1955, Shelden and associates³⁰ described the first PT, using a slotted needle to guide a cutting trocar into the trachea. This technique was abandoned after fatalities resulted from trocar lacerations of vital structures adjacent to the airway.^{31,32} In 1969 Toye and Weinstein³³ described a modified Seldinger technique in which a splitting needle was inserted into the trachea, and through this a guidewire was placed. A single lead dilator was passed over the guidewire, the needle split away, and the tracheostomy tube placed. This technique had a 1% incidence of perioperative death and a 6% incidence of paratracheal insertion, which ultimately caused it also to be abandoned.³⁴

In 1985, Ciaglia and colleagues,³⁵ drawing from experience with cricothyroidotomy, described a true Seldinger technique for quick and easy bedside tracheostomy: percutaneous dilational tracheostomy (PDT). In this technique, multiple curved dilators of gradually increasing size are placed over a guidewire, creating an opening for a tracheostomy tube.

Subsequently, several different versions of PT have been described. In 1988, Hazard and associates³⁶ had few complications using three straight dilators instead of Ciaglia's seven curved dilators. In 1989, Schachner and colleagues³⁷ reported a dilating forceps technique (Rapitrac), which is no longer available for use because of its high incidence of complications. In 1990, Griggs and coworkers³⁸ described passing a blunt-tipped modified Kelly forceps over a guidewire to allow dilation of an aperture adequate to place a tracheostomy tube (guidewire dilator forceps [GWDF] technique). This technique is similar to the Rapitrac, but with a lower incidence of complications. In 1999, Ciaglia developed a soft-tipped, tapered dilator (Blue Rhino, Cook Critical Care, Inc., Bloomington, IN) that was used to create a stoma via a single-step dilation.³⁹ This approach replaced the multiple dilations necessary in Ciaglia's original kit, theoretically reducing complications and the time necessary to perform PDT. Fantoni's translaryngeal tracheotomy technique was introduced in 1993 and modified in 1996,⁴⁰ in which a guidewire is directed in retrograde fashion from the trachea to the mouth over which a cuffed cone-cannula is

placed. The cannula is drawn through the neck, and a cuffed tube is placed in the trachea over the cannula as it is removed. The PercuTwist, developed in 2002, uses a dilator with a threaded screw to allow the insertion of a 9-mm tracheostomy tube.⁴¹ The latest modification of the Ciaglia technique of PDT was developed in 2005 and uses balloon dilatation to create the stoma (Blue Dolphin, Cook Critical Care, Inc., Bloomington, IN).^{42,43}

THE ARTIFICIAL AIRWAY

In critical care medicine, regardless of the patient's diagnosis, there are four indications for placement of an artificial airway, which can be either an endotracheal or tracheostomy tube: (1) relieving airway obstruction, (2) providing mechanical ventilation (MV), (3) preventing aspiration in the unprotected airway, and (4) facilitating tracheobronchial toilet.^{44,45}

Intubation and tracheostomies are performed not because of a specific disease, but because an indication is present as a result of disease. Patients do not need intubation because they have chronic obstructive pulmonary disease or have taken a drug overdose; rather, they require ventilatory support or cannot protect their airway. In examining the rationale for intubation or tracheostomy, clinicians working in the ICU should identify the patient as having an indication for an artificial airway, and before it is removed, there must no longer be an indication for an airway.

Although tracheostomy was considered the emergency airway of choice in the past, now endotracheal intubation is preferred for initial airway management. This is because more practitioners are familiar with endotracheal intubation (which requires less specialized equipment and training), and studies indicate that, in the emergency setting, endotracheal intubation has fewer life-threatening complications⁴⁶⁻⁴⁸ such as bleeding and pneumothorax, which are extremely rare. Independent of esophageal

placement, mortality rate from endotracheal intubation is 0.05%, but ranges from 1% to 2% for emergency tracheostomy.²⁹ Tracheostomy should be considered an elective or semielective procedure when the airway is already secured.

Occasionally, endotracheal intubation under direct laryngoscopic visualization is not the initial airway management of choice because of massive facial trauma, tracheal obstruction, or anomalous anatomy.^{49,50} In such cases, endotracheal intubation sometimes can be facilitated through fiberoptic bronchoscopy.⁵¹ When intubation is impossible even with bronchoscopy, or when bronchoscopy is unavailable, the preferred emergency airway procedure is cricothyroidotomy.^{52,53} The primary role of tracheostomy is long-term airway care for patients who initially were treated with ETs or cricothyroidotomies, although reports of PT performed in an emergency setting have been published.⁵⁴⁻⁵⁷

TIMING OF TRACHEOSTOMY

The question as to when to replace an ET with a tracheostomy tube is a subject of much discussion, remaining highly controversial independent of technique. Beatrous⁴⁴ stated in 1968 that, "Timing is an aspect of tracheostomy that deserves much more emphasis than it is apparently receiving. Delay defeats the purpose of the operation."

The debate as to when to replace an ET with a tracheostomy tube centers on the advantages and disadvantages of the tracheostomy tube, as listed in Table 14.1.⁵⁸⁻¹²⁶ Unfortunately there are very few definite studies confirming or refuting these advantages.

The decision as to when to perform a tracheostomy is more often based on personal preference of the treating physician than on data. For patients with an airway obstruction that cannot be relieved, tracheostomy is the treatment of choice because it is the only airway that can safely remain long term.^{127,128} In most other situations the decision is not as straightforward as ultimately only 5% to 11% of patients on MV require placement of a tracheostomy tube.

Table 14.1 Advantages and Disadvantages of Tracheostomy

Advantages

Protection from laryngeal injury^{58-75,110,115}
 Security of airway^{69,73-77}
 Facilitation of weaning^{74,78-92,116-121}
 Improved patient comfort and psychological well-being^{74,93,94,122}
 Earlier oral nutrition⁹⁵
 Possibility of speech^{76,95-98}
 Easier nursing care (mouth care, tracheal suctioning)^{73,74,96-98}
 Improved patient mobility^{73,74,111}
 Decreased sedation requirements^{94,123}
 Decreased risk of sinusitis and pneumonia^{73,74,85,87,89,116-118,121}
 Earlier ICU discharge^{86,87,89,91,92,99,116,118-120,121,124}
 Earlier hospital discharge^{89,116,117,124}
 Improved survival^{87,88,91,100,101,121}

Disadvantages

Tracheal complications^{29,69,71,74,102,103,109}
 Procedural risk^{29,44,47,48,73,74,94,103-108}
 Risk of stoma infection^{44,48,74,94,106}
 Risk of cannula displacement^{29,48,74,106}
 Delay in weaning and decannulation^{85,109}
 Delay in ICU discharge^{100,125}
 Increased risk of pneumonia^{29,74,109}
 Poor stoma healing after decannulation^{48,102}
 Poor cosmetic results after decannulation^{48,108}
 Increased awareness of loss of voice, stoma pain, fear of procedures (e.g., suctioning)^{113,114}
 Fear and panic attacks after decannulation^{113,114}
 Increased mortality after ICU discharge with tracheostomy cannula in place¹²⁶

*Improved survival after tracheostomy has not been demonstrated in all studies (see text).
 ICU, intensive care unit.

Nevertheless, those patients account for 26% of all ventilator days and 14% of hospital days.^{101,125,129}

Although the need for tracheostomy sometimes can be predicted early in the ICU course (e.g., neurologic ICU patients with infratentorial lesions who have brainstem dysfunction¹³⁰ or a low Glasgow Coma Scale score^{90,99}), in most situations this is not the case. Finding early clinical predictors that would identify patients who require a tracheostomy is most problematic in patients receiving MV.¹³¹⁻¹³⁴ Many studies from the early and mid-1990s attempted to establish criteria to satisfy the recommendations of the 1989 Consensus Conference on Artificial Airways in Patients Receiving Mechanical Ventilation, which stated that “the decision to convert to tracheostomy should be made as early as possible . . . to minimize the duration of translaryngeal intubation. Once the decision is made, the procedure should be done without undue delay.”¹³⁵

Unfortunately, good studies to determine optimal timing of tracheostomy are difficult to perform. Existing studies tend to be either retrospective reviews, which often include a large number of patients but are prone to bias, or randomized, controlled trials that are generally underpowered owing to the large number of patients required to detect significant outcome benefits.¹²⁹ Multiple publications address the question of timing of tracheostomy in a variety of patient populations.^{85-92,115-120,124,136-138} Most are retrospective reviews of ICU databases in which timing of tracheostomy is retrospectively correlated with multiple outcomes. In these studies, the definition of “early” ranges from 3 to 21 days, and “late” ranges from 7 to 28 days, making it hard to draw any firm conclusions. It seems clear from these studies, however, that the procedural and short-term complications of tracheostomy are low, and that in general the outcome of patients with tracheostomy is at least no worse than that of patients managed with prolonged translaryngeal endotracheal intubation.

Some studies show a decrease in mortality rate in patients with tracheostomy.^{100,101,120,125} However, one has to question if this difference is partly explained by the fact that patients with anticipated high mortality risk are not offered a tracheostomy. A frequent finding is that placement of a tracheostomy reduces time on MV,^{86,87,89-92,101,116,118,119,121} but even this is not consistent. Other studies have shown no change^{85,115,138} or even markedly prolonged times¹⁰⁰ on MV. This may reflect either a less aggressive approach to weaning after a potentially permanent airway has been placed or a selection bias reflecting higher early mortality rate in the patients not receiving a tracheostomy.

Randomized controlled trials of early tracheostomy versus late tracheostomy or prolonged translaryngeal intubation are rare. In 2004, Rumbak and associates⁸⁷ showed that early tracheostomy in critically ill medical patients decreased time on MV, ICU length of stay, and ventilator-associated pneumonia. Additionally, early tracheostomy decreased mortality rate by 50% despite well-matched baseline characteristics. They also evaluated the patients for the most feared complication of tracheostomy, tracheal stenosis, during the hospital course and at 10 weeks. No significant differences in the incidence or severity of stenosis were seen, although there was a trend favoring early tracheostomy.⁸⁷

These findings conflict with the findings of several other randomized controlled trials. A trial by Sugerman and

coworkers⁷² showed no differences in any of the measured outcomes (ICU length of stay, death, and pneumonia). This study was significantly limited by incomplete data collection and physician bias. Another randomized controlled trial in trauma patients by Barquist and associates was prematurely terminated after the first interim analysis with only 60 patients enrolled due to lack of differences in the primary outcomes; ICU length of stay, ventilator-associated pneumonia, and ventilator days.¹³⁶

A well-designed trial in France looked at multiple end points including death, pneumonia, duration of MV, complications, sedation requirements, and subjective patient comfort. There were no differences in any of the parameters, except in late laryngeal complications and patient discomfort. All patients who had an endotracheal as well as a tracheostomy tube during the course of their illness favored tracheostomy. Unfortunately, only 10% to 20% of eligible patients were actually enrolled in the trial and the study was grossly underpowered to detect any significant differences.¹¹⁵ Finally, a study assessing the impact of early tracheostomy (6-8 days) on the risk of developing ventilator-associated pneumonia showed a statistically insignificant trend ($p = 0.07$) toward reduction in the incidence of pneumonia.¹²⁰ Another large trial showed no benefit of early tracheostomy except reduced use of sedatives.¹²³ Interpreting length of ICU and hospitalization data from these trials requires knowledge of post-tracheostomy disposition, which may vary depending on the country in which the study was performed. Specifically, the availability of long-term ventilator facilities might not be apparent.

An older trial in the 1970s by Stauffer and colleagues,⁶⁹ which is frequently quoted as an argument for prolonged translaryngeal intubation, found significantly more complications that were judged more severe in patients who underwent tracheostomy compared to patients with translaryngeal intubation. Most notably, the incidence of tracheal stenosis after tracheostomy was significantly higher (65% versus 19%). Nonetheless, they also found that patients treated with prolonged translaryngeal intubation followed by tracheostomy had significantly more laryngeal injury and an increased frequency of tracheal stenosis compared with patients who underwent tracheostomy after a short period of translaryngeal intubation.⁶⁹

Conclusions from all these studies indicate that a tracheostomy should be offered only to patients anticipated to survive who require secure, long-term airway access. The timing of tracheostomy tube placement should be individualized and depends on three factors: (1) underlying disease, (2) indication for artificial airway, and (3) expected ultimate outcome. An article published in 2012 found that the hospital mortality rate of patients undergoing PDT was 30% with 14-day and 6-month mortality rates of 11% and 40%, respectively.¹²² Predictors of poor short-term outcome were found to be older age, diagnosis of malignancy, cardiogenic shock, and presence of a ventricular assist device. A realistic discussion of prognosis therefore should be part of the informed consent prior to placement of a tracheostomy.

Despite several negative trials that were generally underpowered and with the emergence of bedside PDT, a recommendation for earlier tracheostomy still seems appropriate as the early complication rate in experienced hands is low and is likely outweighed by the probable benefits, especially

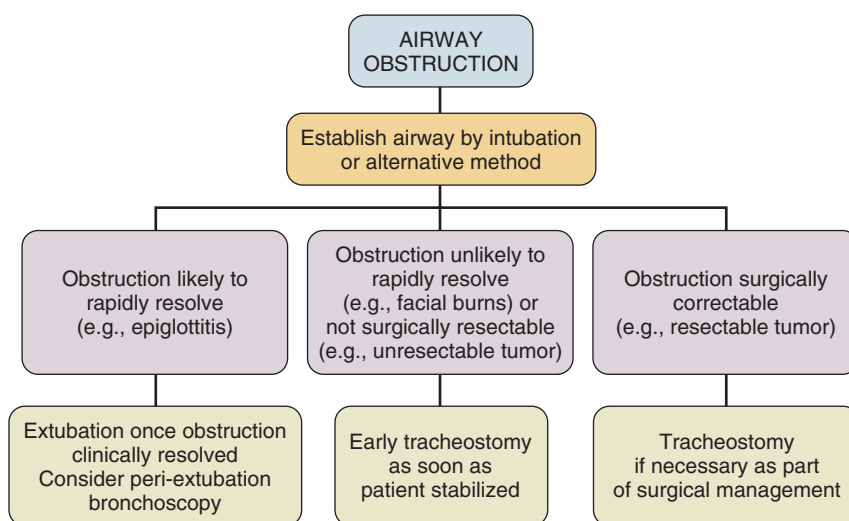

Figure 14.1 Timing of tracheostomy in airway obstruction.

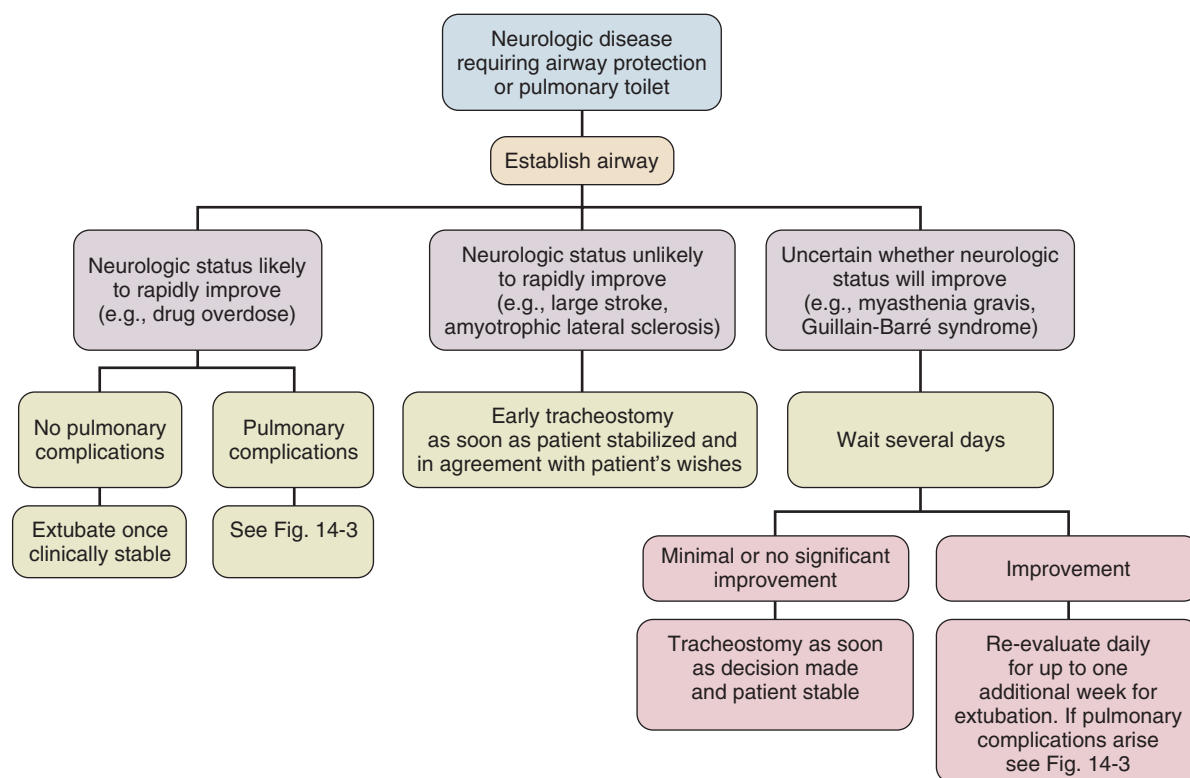

Figure 14.2 Timing of tracheostomy in neurologic disease.

patient comfort. [Figures 14.1 through 14.3](#) provide suggested algorithms regarding the timing of tracheostomy placement based on whether the patient's pathologic condition is primarily upper airway obstruction, neuromuscular, or pulmonary.

UPPER AIRWAY OBSTRUCTION

In patients who have upper airway obstruction, the timing of tracheostomy depends on the likelihood of rapid resolution of the obstruction and whether surgical intervention is required (see [Fig. 14.1](#)).

NEUROMUSCULAR CONDITIONS

Many ICU patients intubated because of stupor, coma, or neuromuscular weakness (see [Fig. 14.2](#)) are susceptible to aspiration, as they may have laryngeal dysfunction and may not be able to generate an effective cough.¹³⁹ In most patients, the duration of the pathologic condition is predictable, either short (e.g., drug overdose) or long (e.g., large stroke, amyotrophic lateral sclerosis).¹⁴⁰⁻¹⁴⁵ In some cases of postoperative weakness, cerebrovascular accident, and peripheral neuromuscular weakness (e.g., Guillain-Barré syndrome, myasthenia gravis), the course is uncertain.^{139,146-149}

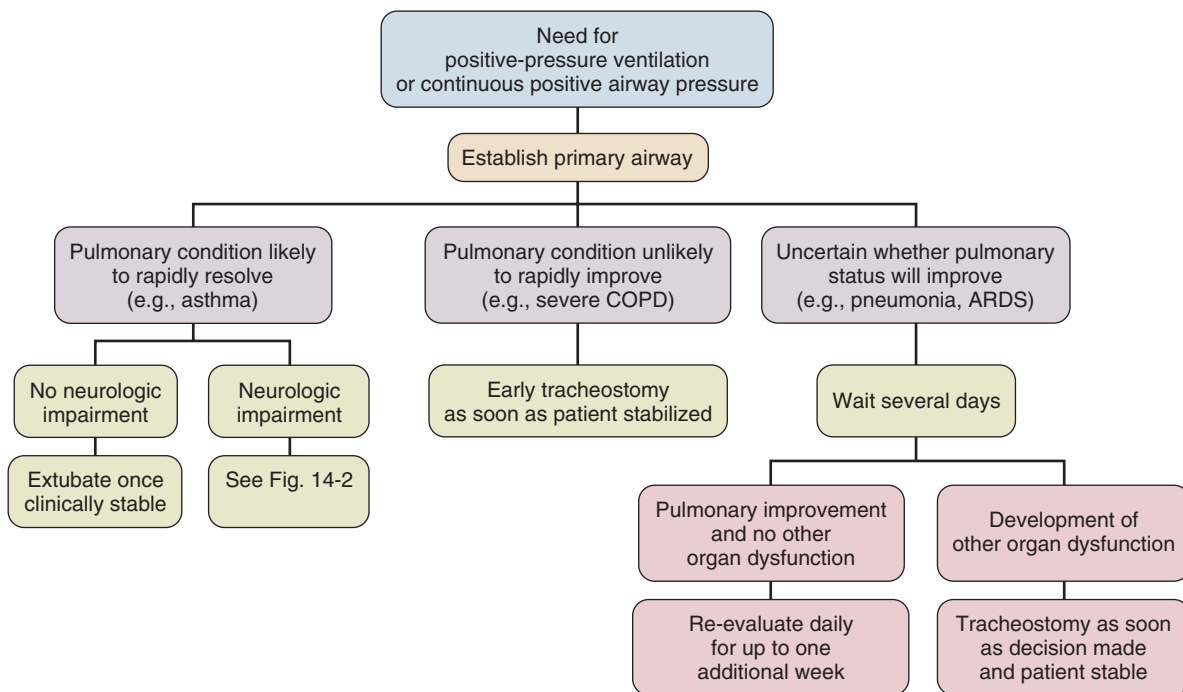

Figure 14.3 Timing of tracheostomy in pulmonary disease. ARDS, adult respiratory distress syndrome; COPD, chronic obstructive pulmonary disease.

A second factor involved in the decision to perform tracheostomy is the coexistence of pulmonary complications, such as atelectasis, pneumonia, or aspiration (see Fig. 14.3).

PULMONARY CONDITIONS

The spectrum of diseases for patients intubated because they require MV is so broad that firm rules regarding tracheostomy have not been established. The approach to the timing of tracheostomy in these situations is difficult because the duration of ventilatory support is frequently hard to predict. This is demonstrated in some randomized studies comparing early and late tracheostomy in which 50% to 75% of patients randomized to delayed tracheostomy did not undergo this procedure because of either death or extubation.^{115,120,150} Despite this and multiple studies not supporting survival benefits or faster liberation from ventilator support but with data supporting improved patient well-being, it is advisable to consider early tracheostomy once the patient has stabilized, if the patient is expected to survive and needs a long-term airway, and a tracheostomy can be safely performed.

However, a recently published paper followed 73 ICU patients who received a tracheostomy and were transferred to a floor experienced in the care of patients with tracheostomies.¹²⁶ Patients who were not decannulated in the ICU had a significantly higher mortality rate compared to the patients who were decannulated prior to transfer (11% versus 26%). The only other factors associated with increased mortality rate were the presence of tenacious sputum at ICU discharge and a body mass index (BMI) greater than 30 kg/m². “The cause of in-ward deaths was cardiopulmonary arrest in 33% of ICU-decannulated patients, versus 90% of those discharged with a cannula in place ($p = 0.08$), most of which occurred overnight.” The authors feel the

most likely cause of death was respiratory arrest that was likely cannula related, suggesting suboptimal monitoring and care for nondecannulated patients after ICU discharge. This study, though very concerning, was a single-center, prospective, observational trial. Therefore, this finding may reflect an institutional problem rather than a problem inherent to the procedure. Nevertheless, this issue needs further investigation.

COMPLICATIONS OF TRACHEOSTOMY

Throughout the history of tracheostomy, complications have been the most scrutinized aspect. Complications have been categorized as occurring during performance of the tracheostomy (procedural), while the tube is in place (in situ), or after decannulation.^{29,102,106} Older studies report a major complication rate of approximately 15% (range, 6% to 66%), with a mortality rate of approximately 1.5% (range, 0% to 5%).^{29,47,48,69,71,102-107,151} More recent studies show generally lower complication rates ranging from 1.4% to 27%, and essentially negligible mortality rate.¹⁵²⁻¹⁵⁸ A recent multicenter review showed that major procedural complications are rare and are only dependent on operator experience, but not surgical technique or location of the procedure.¹⁵⁷

PROCEDURAL COMPLICATIONS

The most common serious procedural complications are pneumothorax (0.9% to 5%) and severe hemorrhage (5%).^{44,47,48,71,103,105,151} Pneumothorax usually results from violation of the pleural space as it ascends into the neck. Operative hemorrhage is usually venous, originating from the anterior jugular venous system, the thyroid gland isthmus,

and very rarely may be arterial from an aberrant vessel. Most of the time bleeding can be controlled by local measures alone, but occasionally will require surgical intervention for hemostasis.¹⁵⁶ Other serious but very rare complications (<1%) include tube misplacement, tracheoesophageal perforation, aspiration, thyroid laceration, recurrent laryngeal nerve damage, and cardiopulmonary arrest.^{29,48,151,152,156} Less serious complications are subcutaneous and mediastinal emphysema, clinically insignificant hypotension, and desaturation.^{152-154,157}

IN SITU COMPLICATIONS

After a tracheostomy tube is placed, it is susceptible to obstruction and displacement, which may be potentially life-threatening, especially if a problem occurs before a secure tract has been formed and is not promptly recognized.^{29,48,106} Tube displacement may result from poor tracheostomy tube selection, excessive patient motion, or careless reinsertion after dislodgement. Obstruction is often caused by tenacious secretions, but can also be caused by positioning of the tracheostomy tube against the wall after poor sizing of the tracheostomy. Use of a double-cannula tube with a disposable inner cannula protects against occlusion by encrusted secretions,^{8,159} though this may delay successful weaning because of the increased outer diameter of the tube.¹⁶⁰

Increasing peak airway pressure, increased resistance during manual bag ventilation, or difficulty passing a suction catheter may indicate tube obstruction or displacement. Providing adequate humidity, adhering to suctioning and tracheostomy care protocols, and minimizing tube manipulation help avert this.^{48,106,151}

Another common in situ complication is stomal infection, which occurs in 36% of all tracheostomies.⁶⁹ Trivial stomal infection can be treated topically.⁴⁸ Necrotizing wound infection can occur, and may extend into the mediastinum, causing life-threatening sepsis.^{154,161} Many patients will have bacterial colonization of the tracheobronchial tree, especially with resistant gram-negative organisms (50% to 66%) making them more susceptible to develop nosocomial pneumonia.^{29,103,127,162}

In contrast to intraprocedural venous hemorrhage, in situ hemorrhage usually results from the tracheostomy tube tip eroding into a major artery, generally the innominate (0.2% to 4%).^{29,69} The resultant tracheoinnominate fistula will present as massive bleeding, sometimes heralded by smaller bleeds or a pulsating tracheostomy tube. Treatment consists of immediate tamponade and operative ligation, despite which tracheoinnominate fistula carries a 75% mortality rate.^{29,48,163} Other in situ complications include mucosal ulceration, tracheal erosion, tracheal dilatation, and very rarely tracheoesophageal fistula.^{48,69,106,164-168}

COMPLICATIONS AFTER DECANNULATION

The most important postdecannulation complication after tracheostomy is tracheal stenosis.^{29,69,71,74,103,155-157,169} It can develop in three distinct areas: subglottic, at the stoma site, or at the cuff site. A mild degree of tracheal narrowing after decannulation at the site of the stoma is very common, and if patients are carefully evaluated with imaging and

endoscopy, tracheal narrowing can be found in 30% to 75% of patients after tracheostomy.^{69,158,169} Most patients with tracheal stenosis remain asymptomatic and require no treatment.⁷⁴ Symptoms generally occur when the tracheal lumen diameter is reduced by either 75% or to less than 5 mm.¹⁰³ Recent studies showed a risk of symptomatic stenosis in 0.6% and 10% of patients who were followed long term.^{157,158,169} Risk factors for the development of tracheal stenosis at the stoma site were found to be hypotension, sepsis, stoma infection, older age, male sex, use of steroids, tight-fitting cannula, prolonged cannulation, and excessive motion. In a study published in 2012 another risk factor for stenosis was obesity with an increase in risk in the obese from 0.4% to 9.9%. This was especially true if prior to the tracheostomy the patient was intubated with an ET greater than size 7.5 (relative risk 27) and if intubation prior to tracheostomy lasted longer than 7 days (relative risk 2.5).¹⁵⁷

Stenosis at the site of the cuff is related to mucosal pressure necrosis, exposing the tracheal rings. As the airway is often chronically colonized this will cause chondritis ultimately leading to tracheomalacia or tracheal stenosis. The introduction of the high-volume, low-pressure cuffs has decreased the incidence of this complication by a factor of 10.¹⁷⁰⁻¹⁷⁴ Despite the use of low-pressure cuffs, Stauffer reported that about 20% of patients required excessive cuff pressures to achieve a seal, though the rate was similar in patients with endotracheal or tracheostomy tubes.⁶⁹ As has been shown, a low-pressure cuff does not guarantee a low pressure, especially in patients with high pulmonary inflation pressures. Therefore, cuff pressures should routinely be measured and maintained at the lowest appropriate level, ideally less than 25 mm Hg. Even this may not prevent tracheal injury because lateral wall pressure varies widely, is unmeasurable, and may compromise local tracheal blood supply.^{166,174-176}

The question whether tracheostomy tubes cause more tracheal stenosis than ETs cannot be answered at this time as most patients who undergo tracheostomy were initially treated with translaryngeal intubation of variable duration, and often require the chosen airway device for a prolonged period. These confounding variables make it impossible to state with certainty if stenosis was caused by the endotracheal or tracheostomy tube unless it is at the site of the stoma. Subglottic stenosis, which is more commonly due to translaryngeal intubation, is more difficult to repair surgically.^{110,177-179} Other late complications, which occur infrequently, include tracheocutaneous fistula, tracheomalacia, tracheal granulomas, vocal cord dysfunction, and cosmetic deformities.^{102,152,180,181}

RISKS OF PATIENT TRANSPORT

A further risk for patients who are having a tracheostomy performed is related not to the procedure itself, but to transporting patients to the operating room. The incidence of harmful events in patients during transport is 33% to 68%,^{182,183} with Waddell reporting that “one patient a month suffered major cardiorespiratory collapse or death as a direct result of movement.”¹⁸⁴ To address this issue and to reduce tracheostomy complications, Ciaglia developed the technique of PDT in 1985.³⁵

PERCUTANEOUS TRACHEOSTOMY

Many descriptive series and reviews have examined short-term and long-term complications of percutaneous tracheostomy (PT)^{104,158,185-195} and prospective comparisons of PT with surgical tracheostomy (ST).¹⁹⁶⁻²⁰³ By virtue of these studies, PT has become an integral part of the care of critically ill patients, with PDT the most common PT performed today.^{204,205} In many institutions PT is the procedure of choice when a tracheostomy is needed for an ICU patient.^{195,206}

When reading and analyzing the literature related to PT, it is essential to know which of the currently available procedures of PT are being discussed: one of the PDTs (Ciaglia Blue Rhino, Blue Dolphin, or the Portex multiple straight dilator kit), Griggs' GWDF, Fantoni's translaryngeal tracheostomy, or Frova's PercuTwist²⁰⁷ (see "History" section earlier).

It is important to realize that all PDT techniques are percutaneous tracheostomies, but not all PTs are PDTs.²⁰⁷ Most PTs reported in the literature have been performed using the Ciaglia dilational technique (PDT),^{104,152,188,194,195,208} followed by Griggs' GWDF technique.²⁰⁸ There is evident confusion with respect to the different techniques of PT, as seen in an article on surgical airway management in the ICU in which the description of PDT is that "sequential dilators are used to enlarge a tract," but the picture of the commercial kit that "has the necessary instruments" for the procedure is one of the single-dilator Blue Rhino.²⁰⁹ Confusion occurs when publications describe PT performed using Portex kits (Keene, NH), but fail to clarify which of the kits that Portex makes for PT was used. One, manufactured in the United States, is made for the Ciaglia PDT technique using three straight dilators. The other is made in Europe for the Griggs GWDF technique.³⁸ Finally, confusion regarding technique of PT is especially evident in most published meta-analyses, with only two that compared studies of only one technique of PT (namely PDT) and ST,^{210,211} and the others comparing at least two different techniques of PT to ST.^{152,212-214}

Each of these techniques has its own particulars with respect to technique and complication rates. When evaluating PT techniques or comparing PT with ST, the technique that is being used must be specified.²⁰⁷ This was not done in many studies of PT^{207,212-214} and significantly affected the conclusions²¹⁵ of the meta-analysis of PT versus ST by Dulguerov and coworkers.¹⁵²

Clear knowledge of the technique and complication rates of the different types of PT will allow an informed judgment as to which of the techniques should be chosen to be performed. Based on the fact mentioned earlier that most reports of PT are of Ciaglia's dilational technique, predominantly using curved dilators (either single or multiple), the most popular technique of PT seems to be PDT. In most studies that compared PT with ST, PDT was used.¹⁹⁶⁻²⁰³ One compared translaryngeal tracheostomy versus ST,²¹⁶ and two others compared GWDF technique versus ST.^{217,218}

Reports by van Heerden and associates,²¹⁹ Nates and colleagues,²²⁰ and Fikkers and coworkers²²¹ have compared short-term outcomes using the Griggs GWDF technique versus PDT. Van Heerden and associates²¹⁹ showed no

difference in complications, Nates and colleagues²²⁰ showed a significantly higher incidence of bleeding using the GWDF technique, and Fikkers and coworkers²²¹ showed a higher rate of minor procedural and postdecannulation complications in GWDF technique. Cantais and associates²²² compared GWDF technique with translaryngeal tracheostomy, finding a higher rate of serious complications in the translaryngeal tracheostomy group. Byhahn and colleagues compared PercuTwist with PDT (single dilator)²²³ and found more patients in whom insertion of the cannula was difficult/impossible with the PercuTwist. Montcriol and coworkers²²⁴ found PercuTwist to take significantly longer than GWDF technique.

In an attempt to reduce the chance of injury to the posterior tracheal wall, and to speed up the procedure, Ciaglia developed the gradually tapered soft Blue Rhino dilator in 1999.³⁹ Two randomized comparisons of multiple-dilator PDT with the single-dilator Blue Rhino PDT^{39,225} showed a shorter procedure duration for the single-dilator PDT. Also, no intervention was required despite a statistically higher incidence of tracheal ring fracture in the single-dilator group in one study.³⁹ In the multiple-dilator group, there were two injuries to the posterior tracheal wall and one pneumothorax.³⁹ The latest development in PDT uses balloon dilation and is a true single-step procedure.^{42,43} Cianchi and associates⁴³ found that balloon dilation took significantly longer than the single-dilator PDT and that limited intratracheal bleeding was more frequent after balloon dilation.

TECHNIQUE

The technique of PDT can be learned by attending a training course or observing the procedure, followed by assisting and performing PDT under supervision until proficiency is attained, which usually occurs after performing 10 to 20 procedures.²⁰³ The operator's initial efforts should be performed under supervision of an experienced operator using bronchoscopic guidance,¹⁵³ in an already intubated patient. It is important to remember that there is a learning curve with this procedure. Complications are more likely to occur early in the practitioner's experience with PDT.²²⁶

Initially, PDT was thought to be contraindicated in emergencies, in children, in obese patients, and in patients who had a previous tracheostomy, uncorrectable coagulopathies, or severe anatomic neck deformities,³⁵ but its performance has been described in all of these groups except children younger than 14 years old.^{54,56,57,185,186,189,195,227-232} We believe PDT remains absolutely contraindicated in young children and patients with certain severe anatomic neck deformities (e.g., fused, anterior flexed neck, overlying neck mass). An emergent PDT to establish an airway should be done only by practitioners with significant experience in the procedure.

Prior to PDT, the patient is placed on 100% oxygen, given glycopyrrolate, intravenous sedation, and a paralytic agent, and positioned supine with the neck hyperextended. The first or second tracheal interspace is identified, and the ET is positioned so that the end of the tube is proximal to the intended tracheostomy site.

The ET is usually positioned by either palpating the ET cuff to identify the tube position,²³³ or using bronchoscopic

guidance.^{104,187,234} Besides facilitating proper tube positioning, using the bronchoscope allows direct visualization of needle insertion, ensuring midline placement and intratracheal insertion of the tracheostomy tube.¹⁰⁴ Marx and Ciaglia²³⁵ who originally recommended nonendoscopic ET positioning, later recommended use of bronchoscopy. Recently, Mallick and colleagues²³⁶ prospectively compared capnography and bronchoscopy to confirm tracheal placement, and Jackson and coworkers²³⁷ retrospectively compared PDT with and without bronchoscopy and found no difference in complications. Other authors^{232,233,238,239} do not routinely use bronchoscopy to perform PDT and recommend its use for training and in selected patients with difficult airways, which has been our experience.

The skin is anesthetized with 1% lidocaine with epinephrine to prevent bleeding, a small localization needle is introduced into the tracheal lumen, and 3 to 5 mL of lidocaine injected. If a bronchoscope is not used, the ET should be gently rotated and oscillated to ensure that it was not impaled by the needle, after which a 15-gauge needle is

inserted through which a guidewire is passed, and the needle removed. To ensure midline placement of the tracheostomy tube the head must remain midline throughout the procedure and the trachea fixed during dilation and tube insertion.

A 1-cm midline vertical or horizontal incision is made and a short punch dilator inserted to enlarge the tract from skin to trachea. A guiding catheter is placed over the guidewire, which remains in place for the duration of the procedure to add stiffness and facilitate passage of the dilator(s), which should be inserted at a right angle to the patient's neck. Dilation of the tract may be performed with multiple curved dilators,³⁵ three straight dilators,^{36,233} a single tapered dilator (Blue Rhino),³⁹ or an expanding balloon (Blue Dolphin).^{42,43} The tract is dilated until an appropriately sized tracheostomy tube (that was previously loaded on a curved obturator) can be inserted (Figs. 14.4 to 14.6, see online video of the technique of PDT). The obturator, guidewire, and guiding catheter are removed; the inner cannula is inserted; and the cuff is inflated. Breath sounds, returned tidal

volume, and cuff pressure must be checked before the tracheostomy is secured. A chest film should be obtained to verify tube position and the absence of barotrauma. In experienced hands, the procedure can be performed in less than 5 minutes.

PERCUTANEOUS DILATIONAL TRACHEOSTOMY VERSUS SURGICAL TRACHEOSTOMY

As mentioned previously, it seems that the Ciaglia PDT has become the benchmark for PT. Although other techniques have been described, none has been as widely accepted,^{33,37,38,40,41,195,208,232} and some are no longer available. Kits currently available to perform PDT contain a single tapered dilator (Cook Blue Rhino, three straight dilators [Portex], or equipment for balloon dilation [Cook Blue Dolphin]). At this point in the history of PT, PDT is the technique that should be the focus of discussion.

Nonrandomized, observational studies of PDT show short-term and long-term complication rates (e.g., mortality, paratracheal insertion, bleeding, infection, and tracheal stenosis rates),^{35,36,104,153,158,185-193,195} that are comparable to or lower than those in similar studies of ST.^{44,47,69,71,74,102-106,108,109} The largest observational study¹⁹⁵ of PDT followed 1000 patients and had an overall complication rate of only 1.4% (1.2% in normal risk and only 1.7% even in high-risk

patients). The authors concluded that PDT “should be considered the gold standard in patients requiring elective tracheostomy in the ICU.”

However, using these articles to justify use of PDT over ST is probably not appropriate, as they are from different eras and there are differences in technique and equipment. Also, complications may have been defined or selected differently. Thus, it is important to examine the prospective trials of PDT versus ST,^{196-203,240,241} which presumably used the same definitions and procedures in both groups. The two latest and largest of these studies found that there was a shorter time to PDT once the decision was made to perform a tracheostomy.^{202,241} Additionally, Silvester and associates²⁰² found a lower incidence of postoperative infection and a trend toward a better cosmetic sequelae in PDT, and Beltrame and colleagues²⁴¹ found that PDT was faster to perform. Others showed a lower incidence of minor in situ complications of PDT.^{196,197,199}

There have been several meta-analyses comparing PT versus ST.^{152,210-214} As mentioned previously, only two^{210,211} examined studies that used only one technique of PT, namely PDT. The others had as many as four different techniques of PT, which will likely affect the results and conclusions of the analyses.^{152,212-214} The largest single-technique meta-analysis of Freeman and coworkers²¹¹ showed that PDT had less procedural and in situ bleeding, a lower stomal infection rate, and lower overall postoperative complications.

Finally, a recent evidence-based analysis of PT versus ST found 13 studies of PT that reached a type II level of evidence. Of the nine that used PDT, eight were prospective studies and one was a meta-analysis. Six had complication rates that favored PDT and two favored ST. However, the authors of this analysis raised several issues: (1) that the findings of improved outcomes of PDT were based on significant reduction of minor complications, but there were no differences in major complications; (2) that the patient selection was biased in favor of PDT by excluding high-risk patients; and (3) that there was no consistent long-term follow-up.²⁴²

What can be said is that PDT has been shown to have a shorter procedure time than ST.^{196,197,241} It has also been shown to have less delay from the time the decision to perform the tracheostomy was made until the procedure was performed.^{202,215,241} Some data suggest that this may shorten ICU stay and time on the ventilator (see Table 14.1). Bedside PDT eliminates the need for transport to the operating room, reducing the morbidity and mortality rates for intrahospital transport¹⁸²⁻¹⁸⁴ and has been shown to be more cost-effective than ST because of decreased utilization of resources.²⁰¹

Although the complication rate of PDT has not been shown conclusively to be lower than that of ST, it appears at least as low and may be lower. The convenience and ease of performing PDT afford flexibility in managing patients. In addition, PDT offers the advantage of avoiding the inherent morbidity and mortality risks of patient transport to the operating room and decreasing cost. Although there will always be indications for ST, either at the bedside or in the operating room, PDT seems to be a reasonable alternative that intensivists, anesthesiologists, and surgeons can and should learn to perform.

KEY POINTS

- Artificial airways are placed for one of the following indications: relieving obstruction, providing MV, preventing aspiration, or tracheobronchial toilet.
- Tracheostomy usually is performed as a replacement for a previously established airway. Whenever possible, tracheostomy should be performed in a controlled setting with an artificial airway already in place.
- As a long-term airway, a tracheostomy has several advantages over an ET (e.g., protection from laryngeal injury, airway security, patient comfort and mobility, and easier nursing care). More data are needed to determine if tracheostomy facilitates weaning, allows earlier ICU discharge, or has fewer long-term complications.
- Patients who require a tracheostomy must be identified as early as possible, and the procedure must be performed without delay to minimize the duration of translaryngeal intubation.
- Complications from tracheostomies can be procedural, in situ, or late and range from 1.4% to 27%. The mortality rate for tracheostomy is less than 1%.
- PDT is an alternative to ST. Complications, morbidity, and mortality rates are comparable with those of ST. As more practitioners become familiar with PDT, it may become the procedure of choice for ICU patients.
- Several significantly different techniques of PT have been described with different complication rates. Practitioners need to be clear about which technique of PT is being used or discussed.

COMPLICATIONS

IMAGING

Chest thoracostomy chest tubes can be lifesaving. Decisions regarding chest tubes can be confusing, however, and chest tubes can be dangerous if placed when not indicated or by inexperienced personnel without proper supervision. The technique, indications, and potential complications of chest tubes should be well known to health care personnel working in the intensive care unit (ICU), as should management after placement. A nonfunctioning or malpositioned chest tube provides misleading information to the managing clinicians.

HISTORY

Hippocrates drained an empyema using a metal tube.¹ Playfair developed underwater seal drainage of chest tubes in 1875.² Credit for the invention of the chest tube is usually given to Hewett,³ who in 1876 devised a system of continuous drainage of the empyema cavity using a rubber catheter that drained into a glass jar filled with a weakly antiseptic solution.⁴ Use of the chest tube was not widely adopted, however, until the 1917 influenza epidemic.⁵ Closed tube thoracostomy drainage of the pleural space after thoracotomy was first reported by Lilienthal in 1922.⁶

ANATOMY AND PHYSIOLOGY OF THE PLEURAL SPACE

The pleural space is the interface between the chest wall and the lung and represents a critical component of pulmonary function. The visceral and parietal pleurae are composed of a single layer of mesothelium. The blood supply of the parietal pleura is of systemic origin (intercostal vessels), whereas the blood supply of the visceral pleura is

of pulmonary origin (pulmonary artery and veins). The bronchial arteries may contribute significantly to the blood supply of the visceral surface.⁷

Both pleural surfaces are lined by an extensive lymphatic network that ultimately drains into the thoracic duct via the mediastinal (visceral) and intercostal (parietal) lymph nodes. There are extensive communications between lymphatics above and below the diaphragm.

Pleural fluid may originate from three sources—parietal capillaries, visceral capillaries, or interstitium. Starling's law of transcapillary exchange governs the movement of fluid across the pleural space. The pressure in the capillaries of the visceral pleura is less than that in the parietal capillaries because it drains into the pulmonary venous bed. The net hydrostatic pressure (35 cm H₂O) favors movement of fluid from the parietal pleura to the pleural space (Fig. 15.1). This pressure is derived from the subtraction of -5 cm H₂O (pleural pressure) from 30 cm H₂O (parietal hydrostatic pressure). This net hydrostatic pressure is opposed by the net oncotic pressure (29 cm H₂O), which is derived from the subtraction of 5 cm H₂O (pleural oncotic pressure) from 34 cm H₂O (plasma oncotic pressure). A gradient of 6 cm H₂O (34 - 29 cm H₂O) favors pleural fluid formation.⁸ The pleural lymphatics prevent the accumulation of this pleural fluid. Stomas, unique to the parietal pleura, facilitate communication between the pleural space and the capillaries. It is estimated that this mechanism allows clearance of 20 mL of pleural fluid per hour per hemithorax in a 70-kg human.^{9,10} The lymphatic network clears protein from the pleural space; smaller molecules can be directly absorbed by the pleural capillaries. Intercostal and diaphragmatic muscle activity influences the rate of lymphatic flow. Hypoventilation and anesthesia reduce lymphatic flow and the rate of absorption of protein.¹¹

DRAINAGE SYSTEMS

The original three-bottle system has been compartmentalized into a plastic unit that is easily transportable and readily pressure-adjustable, consisting of a trap bottle, a water-seal bottle, and a manometer bottle (Fig. 15.2). The trap bottle collects the pleural fluid. The water-seal bottle prevents air from returning to the pleural space during the negative pleural pressure phase on inspiration. The manometer bottle uses the distance below its fluid line to generate a negative pressure when suction is applied. For example, 20 cm of water generates a -20 cm H₂O pressure.¹² Modern collection and suction systems use a single compartmentalized system (Fig. 15.3).

INDICATIONS AND CONTRAINDICATIONS

SIMPLE PNEUMOTHORAX

Pneumothorax is defined as air that has entered the pleural space, either spontaneously or as a result of traumatic tears

Figure 15.1 The direction of fluid movement across the pleural space is shown, moving from the parietal through the visceral pleural surface where transport into the lymphatic system occurs.

in the pleura after chest injury or after invasive procedures. Treatment of pneumothorax entails removing air from the pleural space, reexpanding the underlying lung, and preventing recurrence.¹³ If the patient is clinically stable, the treatment depends on the size of the pneumothorax and whether or not the patient is mechanically ventilated. If the pneumothorax is small, and the patient is not mechanically ventilated, the pneumothorax can be observed. If the pneumothorax is large, or the patient is mechanically ventilated, a chest tube should be placed.¹⁴ A large pneumothorax is defined as being greater than 15% to 20%.¹⁵ Needle aspiration has also been described as a consideration for treatment of spontaneous pneumothorax. However, a repeat chest radiograph must be obtained to assure no recurrence in which case a chest tube would be required.¹⁶

If an occult pneumothorax is identified, which is a pneumothorax found incidentally on computed tomography (CT) scan without evidence clinically or on chest radiograph, observation may be an option. The optimal management remains controversial with regard to tube placement; however, two retrospective reviews demonstrate safe observation without tube placement in patients requiring positive-pressure ventilation.^{17,18}

TENSION PNEUMOTHORAX

Tension pneumothorax is a life-threatening clinical situation that requires emergent and immediate treatment (Fig. 15.4). Air collects and builds up pressure in the chest cavity through a tear in the lung or bronchial tree. Air enters the chest with each mechanical or spontaneous breath, with no route for escape. Initially, the affected lung simply collapses, but as tension increases, the diaphragm flattens, and the mediastinum is shifted toward the contralateral side.¹⁹ The contralateral lung is compressed, further decreasing effective ventilation. The great vessels also are compressed, and venous return is reduced drastically. This reduction in venous return results in rapid and disastrous cardiopulmonary collapse.²⁰ The diagnosis is ideally made on a clinical basis, and treatment is initiated without waiting for radiographic confirmation. Any tension pneumothorax should have immediate large-bore needle decompression. A readily available large-bore angiocatheter is preferentially inserted in the second intercostal space at the midclavicular line. A rush of pleural air under pressure confirms the diagnosis and location. After decompression (conversion to a simple pneumothorax), the catheter is left in until a tube thoracostomy has been placed.²¹

Figure 15.3 Modern drainage system.

Figure 15.4 Chest radiograph shows a left-sided tension pneumothorax with mediastinal shift to the right.

PLEURAL EFFUSIONS

Pleural effusions, both transudative and exudative, are frequently seen in the ICU. The incidence of pleural effusions in the ICU varies with screening methods, from approximately 8% for physical examination to more than 60% for routine ultrasound.^{22,23} Several factors contribute to the

Figure 15.5 An empyema is shown in the right pleural space. Note the thickened pleura surrounding the collection, characteristic of this diagnosis.

occurrence of pleural effusions in ICU patients. Large amounts of intravenous fluid are often administered during the first few days to patients admitted for shock. Pneumonia also is common as a reason for ICU admission and as a complication of mechanical ventilation. Heart failure, atelectasis, hypoalbuminemia, and liver disease are present in many ICU patients. In surgical ICUs, cardiac or abdominal surgery is often followed by specific, large, protracted pleural effusion; in multiple-injury patients, hemothorax is possible.²⁴ The criteria of Light and colleagues,²⁵ which are based on the ratio of protein or lactate dehydrogenase levels in the pleural fluid and blood, differentiate exudates from transudates with a negative predictive value of 96% and a sensitivity of 98%.²⁴

Provided that basic rules are followed, thoracentesis is safe in ICU patients.²² A chest tube may be placed for large or symptomatic pleural effusions. The optimal drainage duration for uninfected pleural effusions has not been established. A reasonable approach may be to remove the chest tubes when drainage decreases to less than 200 mL/day.²⁶

In the evaluation of a parapneumonic effusion or empyema, if the thickness of the pleural fluid is more than 10 mm on a decubitus radiograph, or if the pleural fluid is of similar depth and loculated, the pleural fluid should be examined to determine the stage of the effusion. Drainage of an infected pleural space is required to achieve source control as a key component of treatment (Fig. 15.5). If the fluid is removed completely and does not reaccumulate, no additional therapy need be directed toward the effusion. At the time of the initial therapeutic thoracentesis, the pleural fluid should be sent for Gram stain and culture and analysis of leukocyte, lactate dehydrogenase, glucose, and pH levels. Indicators of a poor prognosis from the pleural fluid include positive Gram stain or culture, glucose less than 60 mg/dL, lactate dehydrogenase more than three times the upper limits of normal for serum, or pH less than 7.20.

If the therapeutic thoracentesis removes all of the pleural fluid and the fluid recurs, the next step is guided by the initial pleural fluid findings. If none of the poor prognostic

indicators is present, no invasive procedures are indicated if the patient is doing well clinically. If any of the poor prognostic indicators were present at the initial thoracentesis, a second therapeutic thoracentesis should be performed, and the pleural fluid should be reanalyzed. If the pleural fluid accumulates a third time, a small chest tube should be inserted into the pleural space, unless none of the poor prognostic factors were present at the time of the second thoracentesis.²⁷ If the patient shows signs of systemic infection, and fluids have been inadequately drained, an open thoracotomy and drainage may be required.^{28,29}

When a hemothorax is suspected, the essential management, along with appropriate resuscitation, is intercostal drainage. This achieves two objectives: first, to drain the pleural space, allowing expansion of the lung, and second, to allow assessment of rates of continuing blood loss. After satisfactory resolution of hemothorax managed with intercostal drainage alone, the drain should not be removed too promptly. Other circumstances permitting, the patient should be mobilized fully with adequate thoracic physiotherapy. These measures should allow optimal drainage of the pleural cavity.³⁰ Complete drainage of blood also prevents empyema and fibrothorax.³¹

Pneumomediastinum is usually a self-limited entity (Fig. 15.6). It follows alveolar rupture into the pulmonary interstitium and is produced by an acute episode of high intrathoracic pressure. The differential diagnosis includes cardiac, pulmonary, musculoskeletal, and esophageal causes. Spontaneous pneumomediastinum is usually a self-limited clinical entity.³² Coupled with positive-pressure ventilation or subcutaneous emphysema, however, cautious observation is recommended owing to the possibility of a pneumothorax leading to tension pneumothorax.

There is no good evidence to support prophylactic chest tubes with high levels of positive end-expiratory pressure. These tubes may be difficult to place and may create more issues. A patient on high positive end-expiratory pressure should be closely observed for any evidence of pneumothorax. If this should occur, a chest tube should be placed at that time.

Contraindications to chest tube placement are mainly relative. The most common would be coagulopathy. If the

draining indication is less than urgent and can be delayed until the coagulopathy can be corrected, the procedure should be postponed. If chest tube placement is emergently needed, one must proceed with caution and actively correct the coagulation issues while proceeding with the tube thoracostomy.

CHEST TUBE SIZE

There is some difference of expert opinion as to optimal chest tube size for various indications. Medicine in general is always moving in the direction of less invasive, smaller, more focused and direct treatments for issues that require some type of intervention. Chest drainage is no different. In an effort to determine the best size tube, two laws are quoted. The first is Poiseuille's law, which states that flow through a tube depends on the internal diameter (D) and length (L) of the tube, the viscosity of the liquid (η), and the pressure difference between its ends (ΔP):

$$\text{Flow rate} = (\pi/128)(D^4\Delta P/\eta L)$$

If the diameter of the tube is doubled, flow increases by a factor of 16, implying that a small increase in the size of the drainage tubes would result in substantial improvements in the flow rates.³³

Another formula key to chest tube size selection is the flow rate of the air or the liquid that can be accommodated by the tube. The Fanning equation determines the flow of moist gas with turbulent flow characteristics through a chest tube:

$$v = p^2 r^5 P / fl$$

where v is the flow, r is the radius, l is the length, P is the pressure, and f is the friction factor.^{12,34-36}

In an in vitro study, Park and coworkers³⁷ measured flow rates of different viscosity fluids (serous, blood, pus) through catheters of different diameters, ranging from 6F to 18F, and found that flow rates increased for larger catheters as predicted by Poiseuille's law. At catheter sizes larger than 7F, however, the differences were small.

Reports on drainage techniques suggest that before drainage of a collection, diagnostic needle aspiration should be performed, initially with a 22-gauge needle and, if this is unsuccessful, subsequently with a 20-gauge or 18-gauge cannula.³⁸ It has been postulated that if pus can be aspirated by such a needle, it should be drainable through a catheter twice the size (i.e., >6F).³⁹ As such, if drain patency can be maintained, the maximum flow rate of the catheter is unlikely to be the limiting factor for most pleural collections.³³

Given the variety of liquids and accompanying pleural debris that may be drained by a chest tube, no single formula exists for flow of these many materials. The principal determinants of airflow through a tube, bore and length, are logically key determinants of flow for various pleural liquids, including blood and pus. Chest tube selection must take into account not only what material is being drained but also its rate of formation. Ongoing production of more viscous fluids requires a larger bore tube than for a similar volume of air produced.⁴⁰

Figure 15.6 Pneumomediastinum (arrow). The pneumomediastinum occurred during a forceful singing period.

In our institution, we have had good success with small tubes placed under radiologic guidance into empyema cavities. These small catheters also have complemented larger tubes that have drained most of the chest but have left small residual pockets, which would be difficult to access blindly with large, less flexible tubes.⁴¹

TECHNIQUE OF INSERTION

When inserting a chest drain for the first time, regardless of the technique, the procedure should be proctored by an experienced supervisor whenever possible. The procedure can be lifesaving or life-threatening, depending on how it is done. Many things should be verified before any skin incision or needlestick is performed. The patient should be well informed as to what is going to happen and why and must give consent. The chest radiograph should be present at the procedure, and the date, patient's name, and affected side should be confirmed by the operator and one other health care professional. Next, all instruments should be confirmed to be present at the procedure. Someone should be available to get additional items needed during the procedure and to reassure the patient during the procedure.

Mild sedation or anxiolysis is typically needed before the procedure, and intravenous access is essential for the ability to give intravenous pain medication. If the procedure is done carefully and with good local anesthesia, there is usually minimal to no need for intravenous sedation. Coagulation parameters (i.e., prothrombin time, partial thromboplastin, and platelets) should be confirmed to be normal or, if abnormal, adequate for coagulation (typically platelet count 50,000/ μ L and international normalized ratio ≤ 1.5 IU). Most hospitals have closed tube thoracostomy trays premade; however, the components that should be available are as follows⁴²:

1. Skin antiseptic solution
2. Sterile drapes
3. Syringes—10 mL \times 3
4. Needles—21-gauge, 23-gauge, 25-gauge
5. Local anesthesia—1% or 2% 10 mL lidocaine
6. Scalpel—No. 11 or 15 blade
7. Sutures—2-0 silk (to anchor tube) and 3-0 nylon (to close site when tube is removed if desired)
8. Heavy scissors
9. Drain sponge dressings and 4 \times 4 dressings
10. Curved hemostat clamps
11. Clamp for chest tube
12. Underwater seal collection system
13. Sterile chest tube—sizes 24F and 32F (depending on what is found to be drained; blood or pus should be 32F, air or fluid can be 24F)
14. Syringes or specimen cups for culture

The patient should be positioned supine with the head of the bed elevated to 30 degrees and the arm held behind the head or abducted to 90 degrees if placement behind the head is impossible. Mark the site of insertion with indelible marker so it is not removed with the skin preparation.

Insertion should be in the “safe triangle” illustrated in Figure 15.7. This is the triangle formed by the anterior

Figure 15.7 Position of patient and safe triangle for identification of injection site.

Figure 15.8 Prepared field for chest tube placement.

border of the latissimus dorsi, the lateral border of the pectoralis major muscle, a line superior to the horizontal level of the nipple, and an apex below the axilla. The most common position for chest tube insertion is in the midaxillary line, through the safe triangle. This position minimizes risk to underlying structures such as the internal mammary artery and avoids damage to muscle and breast tissue resulting in scarring. A more posterior position may be chosen if suggested by the presence of a loculus, although this site is more uncomfortable for the patient, and there is a risk of the drain kinking.⁴³

The patient should be prepared and draped in sterile fashion with a wide field (Fig. 15.8), and the operator should be wearing sterile gown, gloves, hat, and mask. Local

anesthesia should be instilled with a 23-gauge or 25-gauge needle making a skin wheal and allowing 2 to 5 minutes for anesthetic to take effect. Deeper infiltration follows with a 21-gauge needle to the intercostal muscles, the area over the rib, periosteum, and parietal pleura (when air or fluid is aspirated, withdraw the needle slightly and reinfiltrate to ensure anesthetizing the pleura).⁴²

A 1- to 1.5-cm incision is made parallel to the rib and down to the subcutaneous fat at the lower border of the rib space to allow for a small tunnel or tract to prevent air from being drawn around the tube and to close the incision when the tube is removed. A vertical or horizontal mattress suture is placed through the incision, tying a knot at the free ends of the suture. This can be used later when the chest tube is removed to close the skin incision. A tract is created using a small curved hemostat by inserting it closed into the incision and gently spreading. It should be removed and reinserted with each spreading maneuver.⁴⁴ This needs to be done slowly and carefully to prevent pain; this is done multiple times continuously using gentle forward pressure toward the upper border of the rib at the intercostal space to be entered. The right hand opens and closes the instrument, and the left hand is placed close to the tip to prevent plunging into the chest (Fig. 15.9). When the intercostal muscle has been dissected, the pleura is entered. There is a

Figure 15.9 Position of hands on hemostat or clamp to minimize iatrogenic injury.

rush of air or fluid. When possible, a gloved finger should be inserted into the chest cavity to ensure there are no adhesions between the lung and the chest wall. This is most important if the patient has had a history of multiple chest tubes or thoracic surgery.

Before beginning the procedure, the tube should be prepared and placed on the sterile field within easy reach. A closed clamp may be passed through the distal hole and out the end of the tube to facilitate placement (Fig. 15.10). This technique may be easier than trying to open the clamp in the intercostal space to advance the chest tube. The tube can then be passed over the clamp in a Seldinger-type technique. Another method is to place the tube in the clamp prior to insertion into the chest. The tube should be positioned against the outside curve of the clamp (see Fig. 15.10). When placed, the tube should be clamped at the distal end to prevent leakage. The tube should be connected to the tubing in a sterile fashion. The clamp can then be removed. Reexpansion of a longstanding pneumothorax may be painful, and reexpansion should be done slowly with use of intermittent clamping. This also is true for chronic pneumothorax and pleural effusions to avoid reexpansion pulmonary edema. Onset of coughing may be a sign of onset of reexpansion pulmonary edema, at which point the clamp should be reapplied. Reexpansion pulmonary edema is discussed later in the section on complications. The tube should be anchored in place with heavy silk suture, and sterile dressings should be applied. A chest radiograph should be obtained and reviewed.

MANAGEMENT OF THORACOSTOMY TUBES

A malfunctioning chest tube can be more dangerous than no chest tube at all. Tension pneumothorax may not be considered as a cause of hypotension if a drainage catheter is in the pleural space; however, if the catheter is not functioning properly, a tension pneumothorax may still be present. In the ICU, especially in the presence of positive-pressure ventilation, a chest tube should be assessed as frequently as any vital sign, ensuring that the tube is patent and draining. If a moderate or large air leak suddenly stops, the tube should be assessed immediately to ensure the tube is not kinked or plugged.

Figure 15.10 Insertion of clamp through distal hole of chest tube to facilitate proper placement of chest tube.

When a thoracic drain has been placed, a chest radiograph should be obtained immediately and reviewed. This is done to confirm placement and assess success of intervention. The amount and character of the drainage or air leak or both should be assessed. A chest radiograph should be done every day for as long as the tube is in place.^{45,46} There is an ongoing debate as to whether to place a tube to water seal or suction when an air leak is present. In two studies of postoperative patients, it was shown that water seal was superior to suction in stopping air leak.^{47,48} In the presence of a large air leak, however, if the pneumothorax increases or a subcutaneous emphysema develops, the tube should be placed back to suction (usually 20 cm H₂O), and a chest radiograph should be immediately obtained. If there is no air leak for 24 hours, and the drainage is less than 2 mL/kg/day, it is safe to remove the tube.⁴⁹ One protocol option begins with thoracostomy tubes placed to 20 cm H₂O suction immediately after insertion.⁴⁵ Tubes are usually assessed for air leak and drainage. Suction is continued if an air leak is present, or if the drainage is greater than or equal to 200 mL in 24 hours. If these criteria are not met, the tubes are placed to water seal. Chest radiographs are not obtained routinely on water seal or before removal. If no air leak is present after 6 hours on water seal, the tube is removed.⁵⁰ If a tube is nonfunctioning, it should be removed. If one chooses to place the tube to water seal before removal, a chest radiograph obtained 3 hours after water seal excludes development of a clinically significant pneumothorax.⁵¹

Clamping a chest drain before removal may be necessary. If an air leak is small and intermittent, clamping followed by chest film may help determine if the patient is likely to develop a pneumothorax after removal.⁵² The house staff and nursing staff must be fully informed, however, so the tube can be immediately unclamped if there is any respiratory difficulty. Clamping of the chest tube in the face of massive hemothorax (1500 mL on placement) also has been advocated; however, in a study creating hemothorax spontaneously in piglets, chest tube clamping did not decrease hemorrhage or mortality rate but worsened gas exchange without improving hypotension.⁵³

There are no data to support prophylactic antibiotic use for chest tube placement in the ICU in nontrauma patients. In traumatic hemothorax, multiple factors, including the condition under which the tube is inserted (emergent or urgent), the mechanism of injury, retained hemothorax, and ventilator care, contribute to development of pleural space infection. The incidence of empyema ranges between 0% and 18% and is decreased with the use of prophylactic antibiotics. Administration of antibiotics for longer than 24 hours does not reduce this risk further.⁵⁴

Obtaining a chest film after removal of a chest tube has been standard practice at most institutions. Timing usually ranges from 6 to 24 hours after the tube is removed. Two retrospective studies and one prospective study concluded that it is unnecessary to obtain routine chest radiographs after chest tube removal.⁵⁵⁻⁵⁷ Other authors advocate obtaining a single upright chest radiograph 24 hours after chest tube removal to evaluate for recurrence of hemothorax or pneumothorax.⁵⁶ In a mechanically ventilated patient, a chest film should be obtained after chest drain removal. A study by Pizano and colleagues⁵⁸ of 214 patients undergoing positive-pressure ventilation concluded that the number

of clinically significant pneumothoraces after chest tube removal seems to be small. The concern persists, however, regarding expansion of a small pneumothorax into a tension pneumothorax. Failure to diagnose a large and expanding pneumothorax could lead to a life-threatening situation. Pizano and colleagues⁵⁸ supported obtaining a chest film within 3 hours after chest tube removal. It also seemed safe to remove a chest tube from patients undergoing positive-pressure ventilation if standard removal criteria were met.^{58,59}

Routine milking and stripping of chest tubes is performed primarily in postoperative cardiac surgical patients. The data do not support routine milking and stripping unless there is clot in the tubing. A significant negative pressure can be generated in the chest during the procedure and could be detrimental. Few such complications are cited in the literature, however.⁶⁰

Postplacement chest radiograph may raise the question of placement in the fissure of the lung, potentially compromising function. This may lead to manipulation to change position. Chest tubes appearing to be in the pleural fissure on plain radiograph function as effectively, however, as tubes located elsewhere in the pleural space.^{61,62}

The positioning of the tubing connecting the chest tube to the drainage system is important. In one study, three tubing positions were studied: straight, coiled, and dependent loop (allowing fluid to collect in a dependent loop with the loop left alone in some, and periodically lifted and drained at 15-minute intervals in others). It was found that the dependent loop left alone did not drain adequately. The straight and coiled positions were optimal for drainage of fluid. If the dependent loop cannot be avoided, lifting and draining it every 15 minutes would maintain adequate drainage.⁶³

Removal of a chest tube is associated with pain. In one study, 4 mg of intravenous morphine was given 20 minutes before removal versus 30 mg of intravenous ketorolac given 60 minutes before removal. Either of these regimens was found to reduce pain substantially during chest tube removal without causing adverse sedative effects.⁶⁴ Another study compared topical lidocaine-prilocaine cream (EMLA) versus intravenous morphine. The investigators found that topical EMLA cream was more effective, but it had to be applied 3 hours before chest tube removal.⁶⁵

Removal of the chest tube must be timed with the breathing pattern of the patient. Some authors advocate removal at end inspiration, whereas others recommend removal at end expiration. The reason some advocate end inspiration is that when the tube is removed the patient may gasp from the pain and may be more likely to suck in air through the site. In one study, a similar rate of postremoval pneumothorax was found. Both methods were found to be safe.⁶⁶ There are two ways to close the sites after the tube has been removed. If sutures were placed, they are tied down. If no sutures were placed, an occlusive dressing must be made with 4 × 4 dressings and tape and petroleum jelly gauze.

COMPLICATIONS

Complications of chest tube placement include improper positioning, bleeding, nerve damage, injury to diaphragm

or abdominal organs, mechanical problems, pain, and bronchopleural fistula. There are multiple case reports identifying issues including atrial fibrillation, pleurocutaneous fistula, extrathoracic herniation of a lung bulla, chylothorax, and neuropathies.⁶⁷⁻⁷⁶ Any structure or organ in the chest or upper abdomen can be damaged or perforated with chest tube insertion. The heart, lung, aorta, vena cava, pulmonary artery, nerves, liver, spleen, and stomach all are vulnerable. Damage is more likely to occur with the use of a trocar, but can occur if the clamp dissecting through the intercostal space is not controlled by the operator. A sudden thrust into the chest, especially in a small chest, can easily reach the mediastinum.

Reexpansion pulmonary edema is a rare and potentially lethal complication of tube placement for pneumothorax, pleural effusion, and severe atelectasis (Fig. 15.11).⁷⁷ The estimated mortality rate is 20%.⁷⁸ Onset of symptoms is often immediate, but can be delayed 24 hours.⁷⁸ Severe coughing heralds the development of pulmonary edema. The patient becomes tachypneic and tachycardic as hypoxia increases. The patient does not respond to oxygen therapy because blood is shunted past fluid-filled alveoli. Rarely, bilateral or contralateral edema develops.⁷⁹ The pathophysiology is complex. Multiple factors contribute to a capillary bed with increased permeability. An inflammatory response occurs when the lung reexpands. This response is believed to be secondary to expansion-related mechanical injury to the alveolar-capillary membrane and reperfusion injury as blood flow returns to the now fully expanded lung.⁸⁰ Patients 20 to 39 years old are more susceptible.⁸¹ The duration of pneumothorax also has been implicated in the incidence of reexpansion pulmonary edema.⁸² Early case series found that spontaneous pneumothorax was present an average of 14 days with a minimum of 3 days before edema would develop.⁸³ The severity of the pneumothorax may be more predictive than its duration in developing pulmonary edema. In the series by Matsuura and coworkers,⁸¹ no patient with a pneumothorax less than 30% of the lung field

developed pulmonary edema. Seventeen percent of patients with total collapse and 44% of patients with tension pneumothorax had this complication. Some authors support slow reexpansion by lower negative pressure as beneficial, whereas others support the idea that it is not so much the degree of negative pressure as the rate of reexpansion that is important.⁸² In clinically stable patients with a large (30% of the lung field) primary pneumothorax, the American College of Chest Physicians recommends either small-bore ($\leq 14F$) catheter or 16F to 22F chest tube placement.¹⁴ Connection to a Heimlich valve or a water-seal device is recommended. If the lung fails to reexpand, suction is deemed appropriate.

The mainstay of therapy remains oxygenation, a low threshold for mechanical ventilation with positive end-expiratory pressure, diuresis if it can be tolerated, and hemodynamic support. Reexpansion pulmonary edema usually resolves in 24 to 72 hours.⁸⁰

IMAGING

Areas in the chest that require chest tube drainage may be loculated owing to adhesions from pneumonias or multiple chest tube placements, making it difficult and dangerous to place a drain blindly into the chest. The use of ultrasound or CT guidance can be invaluable.⁸⁴ Ultrasound and CT also can be used to verify location of tubes previously placed. In one study, 51 pigtail catheters placed under radiologic guidance (CT or ultrasound) were reviewed, with an overall success rate of 88%. The specific success rates were 92%, 85%, and 91% for loculated pleural effusion, pneumothorax, and empyema, respectively. Complications were few and minor.⁸⁵

A chest radiograph should be performed immediately after chest drain placement, but the position of the tube may still be in question. CT has proved to be useful when this occurs (Fig. 15.12). Placement locations such as

Figure 15.11 Chest radiograph shows reexpansion pulmonary edema on left and giant blebs on right.

Figure 15.12 Computed tomography scan shows a loculated pleural effusion with chest tube location (indicated by arrow).

intraparenchymal, intrafissural, mediastinal, chest wall, and abdominal may be identified.⁸⁶ In a study in which CT revealed 28 malpositioned chest tubes among 76 tubes placed in 54 patients, frontal chest radiograph revealed only 6 of the 28.⁸⁷

KEY POINTS

- Chest tube selection must take into account not only what material is being drained but also its rate of formation.
- When inserting a chest drain for the first time, the procedure should be proctored by an experienced supervisor.
- The chest radiograph should be present at the procedure, and the date, patient's name, and affected side should be confirmed by the operator and one other health care professional.
- Insertion should be in the "safe triangle."
- In the ICU, especially in the presence of positive-pressure ventilation, a chest tube should be assessed as frequently as any other vital sign.
- There are no data to support prophylactic antibiotic use for chest tube placement in the ICU in nontrauma patients.
- The mainstay in therapy for reexpansion pulmonary edema remains oxygenation, a low threshold for mechanical ventilation, diuresis (if tolerated), and hemodynamic support.
- CT has proved to be extremely accurate in evaluating the position of a chest tube.

Intracranial Monitoring

Alan R. Turtz

CHAPTER OUTLINE

INTRACRANIAL PRESSURE MONITORING

Ventricular Catheter

Subarachnoid Bolt

Fiberoptic Intracranial Pressure Monitors

Catheter Tip Strain Gauge

CEREBRAL BLOOD FLOW MONITORING

BRAIN TISSUE OXYGENATION MONITORING

SUMMARY

In general, chapters on intracranial monitoring focus on intracranial pressure (ICP). This chapter expands the scope of discussion to include the intracranial monitoring of pressure, cerebral blood flow (CBF), and brain tissue oxygenation.

INTRACRANIAL PRESSURE MONITORING

The history of ICP monitoring dates to 1891, when Quincke measured the cerebrospinal fluid (CSF) pressure via a lumbar puncture.¹ Soon afterward, Cushing showed that as ICP increases and approaches systemic arterial pressure in an animal model, hypertension, bradycardia, and respiratory changes become evident.² The use of continuous ICP monitoring was first described by Guillaume and Janny³ using an intraventricular catheter in 1951. Nine years later, Lundberg⁴ published the first systematic observations of ICP and its response to medical and physiologic interventions. Using ventricular catheters, he showed the clinical value of direct ICP monitoring and described pressure waveforms, of which the Lundberg A wave has the most practical importance in the intensive care unit (ICU). These A, or plateau, waves are characterized by a steep increase in ICP to 60 to 80 mm Hg lasting 2 to 5 minutes or longer, followed by a rapid decrease to near initial baseline pressures. This represents a pathologic response to decompensation of pressure controlling mechanisms.^{4,6} Since these early investigations, CSF pressure and ICP measurement have been developed and refined further.

An ICP monitor is an invaluable research and clinical tool, contributing to the understanding of intracranial pathologic conditions and the assessment of therapeutic interventions. ICP monitoring can be used for patients with intracerebral hemorrhage, Reye syndrome, hepatic encephalopathy, encephalitis, stroke, hydrocephalus, near-drowning, and subarachnoid hemorrhage, but most of the clinical experience with ICP monitoring involves traumatic

brain injury (TBI). In severe TBI, it is important to know if ICP is elevated. Early signs and symptoms of increased ICP include headache, lethargy, nausea, and vomiting. In critically ill patients, these clinical signs may be nonspecific and unreliable.⁶ In addition, the positive trend toward early intubation and sedation, if not pharmacologic paralysis, eliminates the neurologic assessment of a patient with the exception of pupils. Even papilledema, a hard physical sign of increased ICP, is rarely seen acutely in patients with TBI.⁷ Computed tomography (CT) is arguably the most useful diagnostic tool in patients with TBI, but may not reliably determine the ICP.

ICP monitoring in severe TBI has become routine because it facilitates rational management, provides prognostic information, and improves outcomes.⁸⁻¹¹ ICP monitoring can provide crucial information relative to cerebral perfusion pressure (CPP); detect the development or enlargement of a mass lesion, such as contusion or hematoma; facilitate the estimation of intracranial compliance; and be the only parameter to follow in a pharmacologically paralyzed patient, apart from the pupillary examination. It is rarely justifiable to treat a patient for intracranial hypertension empirically without a mechanism for measuring the effect of treatment, such as a clinical examination or ICP.

There are well-defined guidelines for the use of ICP monitoring in TBI, which include patients with an abnormal CT scan and a Glasgow Coma Scale score of 8 or less after cardiopulmonary resuscitation. An abnormal CT scan is defined as one that reveals hematomas, contusion, edema, or compressed cisterns. It also is recommended to consider monitoring head-injured patients with a Glasgow Coma Scale score of 8 or less even if the head CT scan is negative if two of the following three criteria are met on admission: age older than 40, systolic blood pressure less than 90 mm Hg, or signs of posturing (Fig. 16.1).¹²

Although ICP monitoring can be a useful tool in the ICU, this technology has limitations. It is crucial not to assign undue weight to a normal ICP if other clinical information suggests otherwise. ICP does not always increase in the

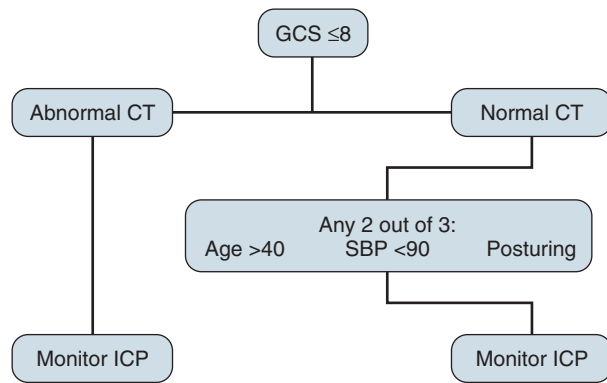

Figure 16.1 Indications for intracranial pressure (ICP) monitoring. CT, computed tomography; GCS, Glasgow Coma Scale; SBP, systolic blood pressure. (From Brain Trauma Foundation, American Association of Neurological Surgeons, Joint Section on Neurotrauma and Critical Care: Management and prognosis of severe traumatic brain injury: Part I. Guidelines for the management of severe traumatic brain injury. *J Neurotrauma* 2000;17:47-69.)

presence of midline shift.^{13,14} More specifically, a temporal lobe mass can herniate over the tentorial edge and cause brainstem compression without a concomitant increase in ICP.^{15,16} Likewise, there is not good correlation between supratentorial and infratentorial pressures,¹⁷ so it is imperative to remember that patients with a posterior fossa mass can deteriorate rapidly without a significant increase in ICP measured in the supratentorial compartment.⁶

ICP waveform analysis includes systolic and diastolic pressures with superimposed respiratory variation; however, the mean pressure is of practical importance. A normal adult mean ICP is 10 mm Hg or less with transient physiologic elevations above this value seen in a head-down position or during a Valsalva maneuver (see discussion of secondary injury in Chapter 67).⁶ The Association for the Advancement of Medical Instrumentation developed standards for ICP monitoring devices that require a pressure range from 0 to 100 mm Hg, an accuracy of ± 2 mm Hg in the range of 0 to 20 mm Hg, and a maximal error of 10% between 20 mm Hg and 100 mm Hg.¹⁸ There are four basic types of clinically useful monitoring systems: ventricular catheter, subarachnoid bolt, fiberoptic device, and catheter tip strain gauge.

VENTRICULAR CATHETER

A ventriculostomy is the gold standard for ICP monitoring. It can be inserted through a twist drill craniostomy at the bedside and can also be used to drain CSF or for the estimation of intracranial compliance. The catheter is connected to a fluid-filled system, which is connected to an external transducer. The transducer converts the measured pressure to an electrical signal, which provides a waveform and numerical value displayed on a monitor through a signal processor. A three-way stopcock is used to divert CSF from the monitor to a drainage bag if needed. This setup allows the catheter to be zeroed as frequently as necessary with the transducer positioned at the level of the center of the brain, which generally corresponds to the external auditory meatus. This system has the potential to be opened and

contaminated and infected. The most significant risk of a ventriculostomy is infection; rates of 27% have been cited,^{10,19-22} although most reported rates are in the 1% to 10% range.^{21,23-26} Infection rates are similar regardless of procedure location (ICU or the operating room).^{20,21,27} Tunneling the catheter subcutaneously to a distant skin exit site seems to reduce the infection risk. Other risk factors for infection include irrigation of the catheter or drainage system and the presence of intraventricular blood.^{20,21,28} Duration of monitoring also may be a risk factor for infection. Some studies have found an increase in infection rates when ventriculostomies were left in for longer than 5 days,^{20,21,25} but more recent data reveal no significant reduction in infection rates when catheters were replaced before the fifth day.²⁹ Likewise, other investigators have found no significant relationship between duration of monitoring and rate of daily infection for 2 weeks.³⁰ The literature on the role of prophylactic antibiotics during external CSF drainage is also variable.^{20,26,28,31} A Brain Trauma Foundation Level III recommendation discourages routine ventricular catheter exchange as well as prophylactic antibiotics for ventricular catheter placement.³² Antibiotic-impregnated catheters have been shown to reduce infection rates³³ and are being used routinely in some centers.

Hemorrhage at the time of placement occurs about 1% to 2% of the time and only rarely needs to be surgically evacuated.^{6,25,34} A more common problem with placement is difficulty in accessing small, compressed, or shifted ventricles, resulting in malposition and a poor waveform. Although a ventriculostomy is generally considered to be the most precise and accurate method of measuring ICP,³⁵ malfunction occurs if the ventriculostomy becomes clogged with air, blood, or debris, or if the ventricles are collapsed around the fenestrations in the catheter tip.

In addition to its primary use as an ICP monitor, a ventriculostomy is commonly used in the ICU as a drain for patients with TBI or hydrocephalus. Common causes of acute hydrocephalus in an adult ICU include cerebellar stroke or hemorrhage, intraventricular hemorrhage, and aneurysmal subarachnoid hemorrhage. A common and often debated concern regarding CSF drainage with a ventriculostomy is that it can cause subfalcine herniation in the presence of a hemispheric mass or upward herniation of the cerebellum in the presence of an infratentorial lesion.³⁶ Under these circumstances, we believe that surgical decompression of the primary mass also should be considered. Another potential risk of ventricular catheter insertion is aneurysmal rebleeding³⁷ after an acute subarachnoid hemorrhage. Our group's opinion is that the benefit of treating hydrocephalus with high ICP far outweighs the small, potential risk of aneurysmal rebleeding, and we have a low threshold for placing a ventriculostomy in these patients.

If a ventriculostomy is primarily used for drainage of CSF, adequate spontaneous CSF resorption must be restored before the catheter can be safely removed. CSF resorptive capacity must be gauged according to the CSF drainage rate. Adjusting the height of the drainage system drip chamber controls the rate of external CSF drainage and the ICP that must be exceeded before drainage occurs. It can be assumed that 1 cm of CSF equals 1 cm H₂O. The height of the drip chamber is measured from the same external anatomic landmark as the ICP transducer, ranging from 0 to 20 cm

(approximately 15 mm Hg) above the external auditory meatus in usual circumstances.

To reduce the amount of external CSF drainage, the drip chamber is usually raised by incremental amounts every 12 to 24 hours. As this is done, CSF resorptive mechanisms are gradually challenged. If CSF resorption is insufficient, most of the CSF continues to drain through the ventriculostomy, but if CSF resorption is sufficient, little CSF drains externally. When CSF resorption seems to be sufficient, CSF drainage is stopped, and ICP is monitored for 24 hours or more to confirm that spontaneous CSF resorption is adequate and ICP will not increase to dangerous levels.

We generally manage ventriculostomies for hydrocephalus by leaving the reservoir open to drain at a specific height above the ear and close it every hour for an ICP reading. In hydrocephalus, the ICP should never be significantly higher than the gradient the patient is draining against (i.e., the height of the drip chamber). We also specify our drainage gradient in millimeters of mercury to correlate the drip chamber to the monitor and manually correlate the height of the CSF column in the drainage system with the monitor as a system check at least daily. A typical order may read: "leave ventriculostomy open to drain at 15 mm Hg (20 cm CSF) above the ear and monitor ICP every hour." ICP readings with the drain open are inaccurate, and the drainage port needs to be temporarily clamped when measuring an ICP. Likewise, the drain should be clamped and placed to monitor when changing position or during transport to avoid overdrainage, which may cause ventricular collapse and possibly subdural bleeding.

SUBARACHNOID BOLT

The subarachnoid bolt technique for ICP monitoring was developed because of concern about the infection rate associated with ventriculostomies, and because small ventricular size after head trauma often makes catheter insertion difficult.³⁸ A subarachnoid bolt is a self-tapping metal or plastic tube that is screwed into a twist drill craniostomy at the bedside. The dura at the base of the bolt is perforated with a spinal needle to allow CSF to fill the bolt, which is connected to pressure tubing filled with preservative-free (non-bacteriostatic) saline that leads to an external transducer leveled to the ear. In contrast to a ventriculostomy, the subarachnoid bolt is only a monitoring instrument; CSF is not withdrawn from it. It usually provides a reliable ICP waveform and pressure reading, but is susceptible to error if the dural perforations become obstructed with blood or debris, or if brain swelling obliterates communication with CSF. Uncapping the bolt to flush debris with 0.2 mL of preservative-free saline solution can restore accurate ICP readings and is unlikely to cause dangerous ICP elevation.³⁹ The subarachnoid bolt tends to underestimate ICP, particularly when ICP is elevated.^{39,40} Because the subarachnoid bolt measures the local ICP at the surface of the hemisphere, it can be inaccurate if a pressure gradient is present between the left and right supratentorial compartments.¹⁹ The existence of compartmental pressure differences has been debated, but such gradients can occur between the left and right hemispheres or the supratentorial and infratentorial compartments and sometimes are only transient.^{19,41-43} This is an important phenomenon to consider, and if a

discrepancy exists between an apparently normal ICP and the patient's clinical condition or CT scan or both, treatment of elevated ICP may be warranted.

The infection risk for subarachnoid bolts is extremely low, and infections are nearly always superficial and rarely involve the brain or meninges.²⁰ No local or systemic infection was reported with the use of subarachnoid bolts in 124 comatose children.⁴⁴ Risk of subarachnoid bolt infection is increased when the bolt is opened and flushed to improve the waveform.²⁰ Subarachnoid bolts are rarely associated with brain injury; however, intracerebral hematoma may occur⁴⁵ if there is a mishap with the drill, or if the needle used to puncture the dura is passed too deeply. Since the introduction of fiberoptic catheters, subarachnoid bolts are being used less often.

FIBEROPTIC INTRACRANIAL PRESSURE MONITORS

Fiberoptic ICP monitors use miniature transducers that are coupled via fiberoptic cables to an external instrument. These monitors can be placed at the bedside through a standard twist drill craniostomy or through a smaller opening made with a 2.71-mm bit. The transducer is incorporated into the end of a tube and can be used alone or in combination with a ventriculostomy. Fiberoptic systems operate by projecting light through an optic fiber to a miniature, displaceable mirror in the catheter tip.⁴⁶ The amount of light reflected to a collecting optic fiber depends on the mechanical displacement of the mirror, which is a function of ICP. Fiberoptic devices can be inserted into the lateral ventricle, the brain parenchyma, or the subdural space. The greatest advantage of fiberoptic catheters is that they do not require fluid coupling for pressure transduction, which avoids the problems of waveform dampening and artifacts from poor coupling. Because they do not require fluid coupling, there also is less opportunity for contamination. The mechanism that does the actual pressure transduction is what is inserted into the patient; the system functions independent of head position, and the monitor is zeroed once before it is placed. This feature also is a disadvantage because the transducer cannot be recalibrated to zero after insertion. System accuracy compared with a ventriculostomy has been shown in the subdural space, brain parenchyma, and ventricles, although the parenchymal fiberoptic pressures may consistently exceed ventriculostomy pressures by nearly 10 mm Hg.⁴⁷⁻⁴⁹ The fiberoptic device has an average daily drift of ± 0.6 mm Hg. Over a 5-day period, there is an average drift of 2.1 mm Hg with a maximal drift of ± 6 mm Hg. This drift over time may be enough to necessitate replacement if ICP monitoring is required for more than 5 days.^{6,49,50}

Complications with the use of fiberoptic catheters relating to hemorrhage^{51,52} and infection⁵¹ have been reported, but our experience is that clinically relevant problems are unusual, particularly with intraparenchymal monitors. We do exercise caution, however, in patients with coagulopathy.

CATHETER TIP STRAIN GAUGE

The catheter tip strain gauge consists of a miniaturized solid-state pressure sensor mounted in a titanium case at the

tip of a long, thin, flexible nylon tube. The transducer tip contains a silicon microchip with diffuse piezoresistive strain gauges that connect to tiny wires that travel the length of the tube. This is a small wire with a diameter of 1.2 mm that can be placed at the bedside. It can be incorporated into a ventricular catheter and used in any intracranial space. This device is accurate with a low daily drift range between -0.125 mm Hg and $+0.110$ mm Hg. It shares many of the advantages and disadvantages of fiberoptic devices,^{6,53,54} but we have found it more cumbersome to place and secure through a bedside twist drill craniostomy.

CEREBRAL BLOOD FLOW MONITORING

The primary objective concerning the ICU management of brain-injured patients is the prevention and management of secondary injury in an effort to prevent ischemia. We typically monitor ICP and mean arterial blood pressure continuously, which allows us to calculate CPP. Under normal circumstances, knowing the CPP allows a good estimation of CBF, which is a more direct measure of blood supply to the brain. In head injury, the relationship between CPP and CBF is less predictable. An ideal intracranial monitor would provide direct, continuous measurements of regional and global CBF at the bedside.

Measuring CBF outside the ICU began with Kety and Schmidt in 1948 and more recently has been done with xenon-enhanced CT,^{55,56} but these methods only give snapshots of CBF and do not allow for continuous monitoring at the bedside.⁵⁷ Continuous monitoring techniques in the ICU are classified as direct or indirect. Direct and continuous monitoring of CBF at the bedside includes laser Doppler flowmetry and thermal diffusion.

The laser Doppler flow sensor (1.5 mm diameter), which emits a monochromatic light, is placed into the white matter through a burr hole. The sensor measures the volume or concentration of red blood cells and their velocity and generates a flow signal. Although laser Doppler flow does allow continuous measurements of perfusion, the sample volume is small (1 mm^3), and only relative changes can be determined. Laser Doppler flow provides a qualitative estimate of regional CBF displayed in arbitrary units.⁵⁸ A quantitative estimate of regional CBF can be acquired with the thermal diffusion method.⁵⁹ With this technique, a probe with two small thermistors is inserted into the brain to measure the tissue's ability to dissipate heat, and a microprocessor converts this into CBF displayed in the standard units of mL/100 g/minute.⁵⁷

An indirect method for measuring blood flow at the bedside is transcranial Doppler ultrasound, which measures mean blood flow velocity in the basal cerebral vessels.⁶⁰ Although not equivalent to volume flow, changes in CBF can be inferred from changes in blood flow velocity.⁶¹ Continuous transcranial Doppler monitoring is still cumbersome, however, because of problems of probe fixation to the head and computer interfacing.⁵⁷ Another indirect way of continuously monitoring CBF at the bedside is by measuring jugular venous bulb oxygenation.

Normal mean CBF is 50 to 60 mL/100 g/minute with higher flow in the gray matter and lower flow in the white

matter. When hemoglobin is fully saturated with oxygen, arterial blood carries approximately 20 mL of oxygen per deciliter to the brain. The oxygen content of venous blood draining the brain varies and depends primarily on how much oxygen the brain extracts. Normal internal jugular hemoglobin oxygen saturation ranges from 55% to 69%, and the normal difference between the arterial and jugular venous oxygen content (arteriojugular difference [AJDO₂]) is 6.3 ± 2.4 mL/dL. Stated differently, under normal circumstances, the brain extracts 6.3 ± 2.4 mL/dL of oxygen from the arterial blood to meet the metabolic needs of the brain.

Normally, the cerebral metabolic rate of oxygen (CMRO₂) is coupled to CBF; as demand increases, supply increases, and vice versa. In head injury, there may be a problem with supply (i.e., CBF may be compromised). If there is inadequate CBF to meet the metabolic demands of the brain, more oxygen is extracted from the available blood. Under this circumstance, the difference between blood going into the brain and blood coming out of the brain increases; AJDO₂ increases as the oxygen saturation in the jugular vein decreases.

AJDO₂ is proportional to CMRO₂ or inversely proportional to CBF or both.⁶²⁻⁶⁵ Assuming that the CMRO₂ is constant, an increase in the amount of oxygen extraction as reflected by a decrease in jugular oxygen saturation (increased AJDO₂) implies that CBF has been compromised. Conversely, if AJDO₂ decreases and metabolism remains constant, we can infer an increase in CBF (i.e., hyperemia). Measuring jugular bulb oxygen can be a useful way to monitor a patient who requires hyperventilation for ICP control (see Chapter 66). Hyperventilation is a powerful tool for reducing ICP and enhancing CPP, but at the expense of increasing cerebrovascular resistance, with the consequent reduction of blood in the brain. The goal of treatment is to prevent ischemia, the ultimate and proximate cause of secondary injury. There is an obvious conflict when attempting to prevent ischemia by reducing the amount of blood delivered to the brain. AJDO₂ is sensitive to changes in cerebrovascular resistance; jugular vein monitoring may reveal inappropriate reductions of CBF as a result of hyperventilation.⁶²

Most of the data concerning jugular bulb monitoring come from the trauma literature. In a prospective study of 353 patients with severe TBI, Cruz⁶⁶ found that outcome at 6 months was significantly better in the patients who had monitoring and management of cerebral extraction of oxygen along with CPP compared with the patients undergoing monitoring and management of CPP alone.

Increased AJDO₂ also can be detected during the early phases of head injury when CBF is pathologically reduced. Typically, the patient is being rescued at the scene, transported, and triaged during this early phase of injury, when CBF is low and ventilation is not carefully titrated. Hyperventilation is frequently used during this vulnerable period, often empirically and sometimes inadvertently.^{62,67} Complicating this scenario is superimposed hypotension and hypoxia, which can occur during the early phases of resuscitation and later in the ICU.⁶⁸⁻⁷⁰ Despite its usefulness, there are significant limitations to this monitoring technique. Measurements can be done by intermittent sampling, which is accurate but is limited by intermittent information, or continuous monitoring of oxygen saturation using

fiberoptic catheters, which require careful maintenance and have reliability issues.^{63,71}

It is easier to use the oxygen saturation of the venous blood in the jugular, rather than direct measurements of oxygen content, but because the percentage of oxygen saturation in the jugular bulb depends on hemoglobin concentration, it cannot be used independently for estimating the relationship between CMRO₂ and CBF. If the patient is anemic, more oxygen may be extracted from the available blood, even under conditions of normal CBF. When measuring oxygen saturation, AJDO₂ needs to be calculated, taking the hemoglobin concentration into consideration. Also, AJDO₂ is an overall estimate of the global relationship between CBF and CMRO₂ and cannot differentiate focal abnormalities. In addition, there is a limit to how much oxygen can be extracted from the available blood. If maximal extraction is reached, and CBF continues to deteriorate, the AJDO₂ does not continue to increase. Under this circumstance, AJDO₂ appears stable despite a progressively worsening situation. Other pitfalls in monitoring AJDO₂ are observed under conditions in which oxygen extraction itself is impaired, such as in cases of mitochondrial dysfunction or a large stroke in which oxygen is not extracted at all.⁶²

Several important technical factors are associated with AJDO₂ monitoring. The side chosen (right or left jugular bulb) is important and can be affected by the side of the brain with the most injury whether or not it is the side of dominant venous drainage.⁷²⁻⁷⁴ How high the tip of the catheter is positioned is another consideration and requires x-ray confirmation.⁷⁵ The speed at which samples are drawn also may affect the results.⁷⁶ Complications are uncommon and include carotid puncture^{63,77} and subclinical internal jugular vein thrombosis.⁷⁷

Ultimately, jugular bulb monitoring is geared toward the assessment of global CBF and cerebral oxygenation and can be useful in guiding therapeutic hyperventilation.^{78,79} In severe TBI, there is enough evidence to recommend its use for titrating the level of hyperventilation;⁸⁰ however, some clinicians find jugular bulb monitoring to be cumbersome, to be prone to artifact, and to have other potential problems with poor data quality.⁸¹⁻⁸³ Because of all of the problems involved with this technique, monitoring of AJDO₂ has not been universally accepted as a useful tool in the routine management of head-injured patients. There remain strong arguments for and against the use of jugular bulb monitoring.^{66,84}

BRAIN TISSUE OXYGENATION MONITORING

Oxygen tension in brain tissue is as close to a gold standard of cerebral oxygenation as we have at the bedside. Brain tissue oxygen tension can be directly measured using a small flexible microcatheter (<0.5 mm in diameter) that is usually inserted into the frontal white matter and fixed onto a special bolt. The normal brain tissue oxygen tension is approximately 40 mm Hg.⁸⁵⁻⁸⁹ Cerebral oxygen tension is generally reflective of CBF and local oxygen extraction. In

this sense, brain tissue oxygen tension may represent the “pool of oxygen” in brain tissue.^{57,90,91} Changes in brain tissue oxygen tension can be used to monitor evolving disturbances of tissue metabolism.^{81,92-94}

Ischemic damage seems to correlate to a brain tissue oxygen tension less than 8 to 10 mm Hg as measured by a Licox catheter (Integra Neuroscience, Plainsboro, NJ).⁸¹ A meta-analysis of three studies including 158 patients with severe TBI found overall cerebral hypoxia, defined as a monitored brain tissue oxygen tension less than 10 mm Hg, was associated with worse outcome and increased mortality rate.⁹⁵ Another study treated 70 severe head injury patients with management directed to maintaining brain tissue oxygenation greater than 25 mm Hg in addition to conventional ICP and CPP management. The results were compared with 53 matched, historical controls treated with conventional management only. The mean daily ICP and CPP and the frequency of episodes of ICP greater than 20 mm Hg and CPP less than 60 mm Hg were similar in both groups. Forty percent of patients with management guided by only ICP and CPP had a favorable outcome compared with 70% of patients with management guided by brain tissue oxygenation.⁹⁶ Additional studies demonstrate a relationship between brain tissue oxygen tension, ICP, and outcome. Recent^{97,98} guidelines suggest a treatment threshold of less than 15 mm Hg,⁹⁹ but the author's preference is to consider treatment at values less than 20 to 25 mm Hg, and a recent study demonstrated a relationship between mortality rate and values less than 29 mm Hg.¹⁰⁰

Local cerebral hypoxia in the presence of normal ICP, CPP, and mean blood pressure may be caused by insufficient arterial oxygenation,⁹² a mismatch between supply (CBF) and demand (CMRO₂),¹⁰¹ or hyperventilation-induced hypocapnia.^{92,102} Hyperventilation can decrease brain tissue oxygen tension because of decreased CBF, which can negate the perceived benefit of improving ICP and CPP.^{81,93,102-108} Hyperventilation has a particular risk of causing cerebral hypoxia when Pco₂ is less than or equal to 30 mm Hg, or within the first 24 hours^{104,105} because of a further reduction of an already reduced CBF.¹⁰⁹ Brain tissue oxygen tension has been shown not to be independently influenced by increases in CPP greater than 60 mm Hg,^{83,93,108} which supports more recent evidence suggesting that maintaining a CPP greater than 60 mm Hg may be unnecessary,^{110,111} and is consistent with current guidelines to keep CPP in the range of 50 to 70 mm Hg in severe TBI.¹¹²

When strategically placed, these monitors are very sensitive in detecting local tissue hypoxia at the tip of the probe. An inherent problem with this technique (as with all focal monitors) is that placement of the probe into the area of interest becomes important.⁵⁷ There are rational arguments as to the best region to monitor. Brain tissue oxygen tension values close to a contusion are smaller relative to a region that looks normal on a CT scan.¹¹³ Some authors recommend monitoring the zone surrounding a contusion because of its high risk of tissue death. Other authors place the probes in uninjured brain with the idea being that a reduction in the brain tissue oxygen tension in the uninjured hemisphere is reflecting a diffuse decrease in arterial oxygenation, an increase in ICP, a decrease in CPP, overaggressive hyperventilation, or some other global event.⁸¹

SUMMARY

Most intracranial monitoring techniques are employed for circumstances involving increased ICP, and ICP monitoring has proved to be useful, reliable, and straightforward. As such, ICP monitoring has become a standard of care and is widely used. It is much more difficult to obtain continuous, clinically useful information with CBF monitoring methods, and these methods have found limited use outside academic institutions. Brain tissue oxygen monitoring is a relatively new technique with mounting evidence to justify continued use, with the hope of providing additional information to the clinician charged with managing the complicated, dynamic pathophysiologic processes of brain-injured patients.

KEY POINTS

- The primary objective concerning ICU management of brain-injured patients is the prevention and management of secondary injury in an effort to prevent ischemia.
- ICP monitoring should be considered for patients with TBI with a Glasgow Coma Scale score of 8 or less.
- ICP monitoring in severe TBI has become routine because it facilitates rational management, provides prognostic information, and improves outcomes.
- It is crucial not to assign undue weight to a normal ICP if other clinical information suggests otherwise.
- A normal adult mean ICP is 10 mm Hg or less with transient physiologic elevations above this value, and normal CPP is generally 60 to 80 mm Hg.
- Ventriculostomies and fiberoptic intraparenchymal monitors are the mainstays of ICP monitoring devices.
- Oxygen tension in brain tissue is as close to a gold standard of cerebral oxygenation as we have at the bedside.

KEY POINTS (Continued)

- Local cerebral hypoxia in the presence of normal ICP, CPP, and mean blood pressure may be caused by insufficient arterial oxygenation, a mismatch between supply (CBF) and demand (CMRO₂), or hyperventilation-induced hypocapnia.
- Hyperventilation has a particular risk of causing cerebral hypoxia when PCO₂ is less than or equal to 30 mm Hg, or within the first 24 hours.
- Maintain CPP in the range of 50 to 70 mm Hg in severe TBI.

ENDOSCOPY IN THE PREGNANT PATIENT

HISTORY

The first documented endoscopic foray into the human body was performed by Philip Bozzini in the early 1800s, when he used a speculum fitted with a candle and mirror to examine the urinary tract.¹ The first gastroscopy was performed in 1868 by German physician Adolf Kussmaul, with a rigid metal tube passed carefully down a patient's esophagus into his stomach. In 1932, Rudolph Schindler, in collaboration with a German engineer, Georg Wolff, developed a semiflexible instrument with a flexible distal shaft. Although this device was hailed as the first safe workable gastroscope, it was not without limitation, including incomplete visualization of the esophagus and stomach, patient discomfort, and absence of photographic documentation.² Fiberoptics were introduced into the endoscope in 1957 by Basil Hirschowitz, and in the 1960s and 1970s further advancements were made with endoscope length, improved visualization, and greater control. Video cameras and monitors were subsequently incorporated into endoscopic technology, allowing others to view what was previously available only to the endoscopist.

Early experience with rigid and semiflexible proctosigmoidoscopes and colonoscopes was disappointing because of the tortuous nature of the sigmoid and colon, and early fiberoptic instruments fared no better. Bergein Overholt made adjustments in torque and control to develop a prototype flexible fiberoptic instrument in 1963.³ The first total colonoscopy was performed in Sardinia, Italy, in 1965. Luciano Provenzale and Antonio Revignas instructed a patient to swallow a piece of polyvinyl tubing, which ultimately emerged from the anus. They attached a side-viewing gastroscope and gently pulled it through the entire colon to the cecum.³ Further refinements were carried out in England, the United States, and Japan, and in 1969 Hiromi Shinya performed the first polypectomy, removing a 1.5 cm pedunculated polyp from the sigmoid colon of a 70-year-old Chinese gentleman.⁴ Shortly thereafter,

colonoscopy became a routine procedure performed by gastroenterologists and other health care providers all over the world.

Endoscopic cannulation of the duodenal ampulla was first accomplished in Chicago by William S. McCune and colleagues in 1968 and is considered the first reported case of endoscopic retrograde cholangiopancreatography (ERCP).⁵ Sphincterotomy was performed in 1974 facilitating removal of two common bile duct stones⁶ and ushering in a new era of therapeutic pancreaticobiliary endoscopy. Today, ERCP remains an invaluable procedure in evaluating and treating diseases of the pancreas and biliary tract.

The first ultrasound examination within the gastrointestinal (GI) lumen was performed by physician John Julian Wild and electrical engineer John Reid in 1956, when they developed the transrectal ultrasound probe.⁷ The incorporation of ultrasound into a standard endoscope occurred in 1976, when Lutz and Rosch passed an ultrasound probe through an accessory port of an endoscope. Further improvements were achieved by Strohman and colleagues and Eugene DiMagno and coworkers, who introduced their own prototype echoendoscopes in 1980. The first endoscopic ultrasound (EUS)-guided fine-needle aspiration was performed on submucosal lesions of the stomach in 1991 by Giancarlo Caletti.⁸

ENDOSCOPIC EQUIPMENT

Today's endoscopes have a control section that is grasped with the left hand and allows for scope control and passage of therapeutic instruments. An insertion tube extends from the bottom of the control section and is grasped with the right hand and passed into the patient. Buttons on the control section allow for suction, insufflation, and washing of the lens. Channel ports distal to the hand controls on the control section allow for the passage of various accessories. Four-way deflection of the distal endoscope tip is performed

through manipulation of the angulation control knobs, which are attached to a series of wires that run the length of the insertion tube. The distal end of the insertion tube, either forward viewing (i.e., endoscope, colonoscope) or side viewing (duodenoscope), contains lenses for illumination and imaging and channel openings for air, water, suction, and passage of instruments.

EUS equipment differs from the standard endoscope in that an ultrasound transducer is incorporated into the distal end of the insertion tube. The transducer emits sound waves that are directed at adjacent tissues and deflected back to the transducer. Individual tissues have different acoustic qualities. Radial and linear echoendoscopes are currently available. Interventional procedures, such as fine-needle aspiration and injections, may be performed safely with the latter echoendoscope.⁹

All video endoscopes have an image sensor called a charge-coupled device (CCD) mounted at the tip of the endoscope, which transmits an image to a video processor for display. Advances in CCD technology have resulted in the current high-resolution or high-definition (HD) endoscopes, which produce signal image resolutions that range from 850,000 pixels to more than 1 million pixels, allowing for detailed inspection of the GI mucosa.¹⁰

The wireless video capsule is a small disposable unit containing a small camera, short focal length lens, light source, two batteries, and a radio telemetry transmitter.¹¹ There are presently three types of video capsules: an esophagus-specific capsule incorporating two CCD chips oriented at 180 degrees, a small bowel video capsule employing a single CCD chip with an 8-hour battery capacity, and experimental colonic video capsules utilizing time-sensitive deactivation and reactivation of the illumination and telemetry elements in order to preserve battery power during small bowel transit. Accessory devices have allowed endoscopic advancement of activated video capsules into the small intestine of patients who have dysfunctional esophageal and gastric motility or altered upper GI anatomy due to prior surgery. The capsule is activated by removal from a magnetic holder, and battery life is approximately 8 hours. Two frames per second are captured by the camera and transmitted to a data recorder that is carried by the patient.

Data are downloaded from the recorder to a personal computer and interpreted. Handheld devices have also recently been developed to allow real-time monitoring of video capsule images.

ANESTHESIA

Choice of anesthesia is based on patient profile, the endoscopic procedure, and preference of the endoscopist, anesthesiologist, and patient. Essential patient information includes prior adverse events from anesthesia, current medications, pertinent medical history, cardiopulmonary status, age, allergies, body habitus, and social history. Patients with alcohol or narcotic dependency may require high doses of opiates and benzodiazepines. Agents such as propofol may facilitate their sedation. Pregnancy should be excluded in any woman of childbearing age. The level of sedation also depends on the endoscopic procedure. Flexible sigmoidoscopy and esophagogastroduodenoscopy (EGD) may require minimal or moderate sedation, whereas more complex and lengthier procedures, such as ERCP and EUS, may require deep sedation or even general anesthesia. Table 17.1 illustrates the different depths of sedation as defined by The American Society of Anesthesiologists Task Force.¹²

Regardless of the type of sedation, cardiopulmonary status should be monitored at all times. Standard equipment should include a pulse oximeter, continuous electrocardiogram, and cyclical blood pressure monitoring. Personnel trained in airway support should always be present. The cardiopulmonary complication rate is 0.005% for EGD and 0.01% for colonoscopy.¹³

Four drug types are commonly used in GI endoscopies: pharyngeal anesthesia, benzodiazepines, opiates, and propofol. Pharyngeal anesthetics, such as lidocaine, benzocaine, and tetracaine, are used to suppress the gag reflex during upper GI tract procedures. These agents, applied by spray or gargling, are active for approximately 1 hour. Potential risks include aspiration owing to loss of gag reflex and, rarely, methemoglobinemia.¹⁴

Benzodiazepines, such as midazolam and diazepam, are used to induce relaxation and amnesia by binding to

Table 17.1 Levels of Sedation and Anesthesia

Anesthesia Management Component	Minimal Sedation (Anxiolysis)	Moderate Sedation (Conscious Sedation)	Deep Sedation/Analgesia	General Anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful response to verbal or tactile stimulation	Purposeful response after repeated or painful stimulation	Unarousable even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

Adapted from Gross JB, Bailey PL, Connis RT, et al. Practice guidelines for sedation and analgesia by non-anesthesiologists. *Anesthesiology* 2002;96:1004-1017.

receptors of the postsynaptic γ -aminobutyric acid neurons. Both have similar properties, with the latter possessing a longer half-life and milder amnestic properties.¹⁵ Onset of action occurs in 1 to 2.5 minutes with intravenous midazolam and 8 minutes with diazepam.¹⁶ Adverse reactions include respiratory depression and hypotension. Overdoses can be reversed with flumazenil, although caution should be used because seizures secondary to acute withdrawal may occur.

Opiates such as fentanyl and meperidine are used for analgesia and sedation. A synergistic effect occurs when opiates are given concurrently with intravenous benzodiazepines. Fentanyl has a rapid onset (1.5 minutes) with a short duration of action (0.5 to 1 hour), whereas meperidine has an onset of 5 minutes and lasts 3 to 5 hours.¹⁶ Common adverse reactions include respiratory depression, hypotension, constipation, nausea, and vomiting. Overdosage can be reversed with naloxone, an opioid antagonist. Long-term opiate users may experience acute withdrawal symptoms with naloxone. Serotonin syndrome may occur if monoamine oxidase inhibitors are used with meperidine.

Propofol, an ultra-short-acting anesthetic agent, has been increasingly used in recent years.¹⁷ Propofol has a rapid onset of action, deeper levels of sedation, and faster recovery time compared with narcotics and benzodiazepines.¹⁸ Propofol use during colonoscopy has been shown to carry a lower risk of cardiopulmonary complications compared with traditional agents.¹⁹ Controversies exist as to its cost-effectiveness and the requirement that it be administered exclusively by an anesthesiologist.

ESOPHAGOGASTRODUODENOSCOPY

EGD is one of the most commonly performed procedures in the world and has become the primary tool for evaluating the esophagus, stomach, and proximal portion of the duodenum. EGD is performed for a wide variety of indications and has a diagnostic and therapeutic role (Box 17.1). There are relatively few contraindications to upper endoscopy (Box 17.2).

EGD is a safe procedure. Perforation occurs in approximately 0.05% to 0.70% of patients,²⁰ with the higher incidence in patients undergoing therapeutic intervention (i.e., biopsy, dilation, mucosal resection). Bleeding may occur as a result of Mallory-Weiss tears, cautery injury, or sclerotherapy injection and after biopsy or polypectomy.

Prior to undergoing elective EGD, patients should be fasting for at least 6 hours. Motility agents, such as erythromycin, may be beneficial in clearing the stomach of blood or food.²¹ In situations of possible airway compromise, elective intubation is reasonable. A 20% incidence of aspiration pneumonia was initially demonstrated after emergent EGD for upper GI bleed.²² A subsequent retrospective study of 220 patients failed to show any significant difference in post-EGD pulmonary infiltrates, witnessed aspiration, cardiopulmonary complications, or in-hospital mortality rate.²³ Despite the lack of a conclusive double-blinded randomized trial, endotracheal intubation may be appropriate in patients with active hematemesis, altered mental status, unstable cardiopulmonary function, or agitation. Alternatives to

Box 17.1 Indications for Esophagogastroduodenoscopy

- Persistent upper abdominal symptoms despite appropriate therapy
- Upper abdominal symptoms associated with signs or symptoms suggesting serious organic disease (anorexia, weight loss) or new-onset symptoms in patients >50 years of age
- Dysphagia or odynophagia
- Esophageal reflux symptoms (persistent or recurrent despite appropriate therapy)
- Persistent vomiting of unknown cause
- Familial adenomatous polyposis syndromes
- Confirmation and specific histologic diagnosis of radiologically shown lesions
 - Suspected neoplastic lesions
 - Gastric or esophageal ulcer
 - Upper tract stricture or obstruction
- Gastrointestinal bleeding
 - Active or recent bleed
 - Suspected bleed (chronic blood loss, iron deficiency anemia)
- Sampling of tissue or fluid
- Documentation or treatment of varices (banding, sclerotherapy)
- Assessment of acute injury after caustic ingestion
- Treatment of bleeding lesions such as ulcers, tumors, vascular abnormalities (electrocoagulation, heater probe, laser photocoagulation, injection therapy)
- Removal of foreign bodies
- Removal of selected polypoid lesions
- Dilation of stenotic lesions
- Placement of feeding or drainage tubes (percutaneous endoscopic gastrostomy, percutaneous endoscopic jejunostomy)
- Management of achalasia (botulinum toxin, balloon dilation)
- Palliative treatment of neoplasms (laser, multipolar electrocoagulation, stent placement)
- Surveillance for malignancy in patients with premalignant conditions (Barrett's esophagus)

Adapted from American Society of Gastrointestinal Endoscopy: Appropriate use of gastrointestinal endoscopy. *Gastrointest Endosc* 2012;75:1127-1131.

Box 17.2 Contraindications to Esophagogastroduodenoscopy

- Risk to patient's health or life judged to outweigh most favorable benefits of procedure
- Conditions in which adequate patient cooperation or consent cannot be obtained
- Perforated viscus—known or suspected

Adapted from American Society of Gastrointestinal Endoscopy: Appropriate use of gastrointestinal endoscopy. *Gastrointest Endosc* 2012;75:1127-1131.

intubation may include pre-endoscopy lavage, overtube placement, or the use of large-caliber endoscopes for suction.

Before administration of anesthesia, patients should be in the left lateral position, with the head elevated and

supported by a pillow. Monitoring devices for vital signs, electrocardiogram, and pulse oximetry are attached, supplemental oxygen should be administered, and a bite guard should be placed in the mouth.

In addition to diagnostic capabilities, therapeutic interventions may be performed during upper endoscopy, particularly in the setting of GI hemorrhage. Several modalities are available for treating GI bleeding, including thermal cautery, electrocautery, needle injection, rubber band ligation, mechanical clips, laser therapy, argon plasma coagulation, and tissue adhesives.

Thermal cautery probes deliver predetermined pulses of heat (250° C) to an endoscopic catheter tip, which is transferred to tissue on contact.²⁴ Thermal probe coagulation can be applied to peptic ulcers, vascular lesions, and Mallory-Weiss tears. Another option for contact thermal coagulation is monopolar or bipolar electrocautery. With electrocautery, electrical current flows from electrode tip through contacted tissue. Monopolar cautery requires attaching an electrical ground to the patient and may cause extensive burn injuries and tissue stickiness. Monopolar cautery is typically not used for hemostasis, but serves a role in snare polypectomy. Bipolar cautery consists of two active electrodes incorporated into a single catheter probe, allowing electrical current to pass from one electrode through the tissue and back to the other electrode. Consequently, bipolar cauterization allows for improved control of coagulation depth.

Injection therapy for nonvariceal and variceal bleeding is performed with sclerotherapy injector needles. Solutions commonly employed are epinephrine in saline (1:10,000) and sclerosing agents, such as polidocanol and ethanolamine. Epinephrine reduces bleeding by vasoconstriction, vessel tamponade, and platelet aggregation.^{25,26} The potential exists for systemic side effects from submucosal injections because plasma epinephrine levels can transiently increase four to five times above basal levels.²⁷ To date, only a single case of hypertension and ventricular tachycardia after epinephrine injection has been reported.²⁸ Sclerosing agents achieve hemostasis through inflammation and sclerosis and have been employed in peptic ulcer hemorrhage and variceal bleeding. Mediastinitis, perforation, stricture formation, and infection are among the reported complications.²⁹

Injector needles are also used in nonbleeding situations. Polyps and superficial tumors can be raised with submucosal injection of saline or epinephrine prior to polypectomy. This technique reduces the likelihood of postpolypectomy hemorrhage or perforation.³⁰ Lesions requiring surgery can be tattooed with ink to facilitate localization by the surgeon.

Rubber band ligation is an effective tool for hemostasis. The delivery system is loaded onto the endoscope tip, and current models allow for deployment of multiple rubber bands before reloading. For variceal bleeding, endoscopic variceal ligation has become the treatment of choice and is superior to endoscopic sclerotherapy in speed of variceal eradication, decreased risk of recurrent bleeding, and fewer complications.³¹ Other uses of banding include gastric varices, peptic ulcers, Dieulafoy's lesions, postpolypectomy hemorrhage, and internal hemorrhoids.

Metal clips, or endoclips, have been used successfully for GI bleeding,³² closure of perforations,³³ anastomotic leaks,³⁴ and prevention of postpolypectomy bleeding.³⁵ The

potential for significant tissue injury is small as only the mucosal and submucosal layers are involved in the grasping.³⁶ The procedure may be technically challenging if massive bleeding is present, or the angle of approach is tangential to the lesion.³⁷

Laser therapy, utilizing neodymium:yttrium-aluminum-garnet (Nd:YAG) or argon, is delivered through probes passed via the endoscope to treat bleeding lesions and for tumor ablation. Nd:YAG and argon lasers differ in the width and depth of tissue effect, with the former having the greater effect.³⁸ Advantages of laser therapy include improved accuracy and not requiring direct contact with the desired target.

Argon plasma coagulation is a noncontact method of hemostasis that delivers argon gas through a catheter probe. The argon gas is ionized, delivering thermal energy to adjacent target tissue. Large areas and tissue not in direct view, due to the tangential arcing nature of the argon gas, can be treated rapidly. Clinical uses include adjunctive ablative therapy after piecemeal resection of colonic polyps, radiation proctopathy, GI vascular lesions, bleeding peptic ulcers, Barrett's esophagus ablation, and palliation of GI malignancies.^{39,40}

Tissue adhesives constitute a newer class of agents for GI hemostasis. The major types of tissue adhesives are fibrin sealants and cyanoacrylate. Fibrin sealants form a coagulum through the interaction of fibrinogen, factor XIII, and thrombin.⁴¹ Extensively used in the surgical fields for tissue adhesion, hemostasis, and wound care, fibrin sealants also have been used endoscopically in bleeding peptic ulcers,⁴² variceal bleeding,⁴³ and GI fistulas.⁴⁴ Cyanoacrylate is synthetic glue that rapidly polymerizes into a solid complex when in contact with water or blood.⁴⁵ Cyanoacrylate has been used with success for esophageal and gastric varices.^{46,47} A serious complication of tissue adhesives is embolization and infarction.⁴⁸

In addition to hemostasis, upper endoscopy is routinely employed for other therapeutic situations. Foreign object ingestion and food bolus impaction occur commonly. Although most foreign bodies pass spontaneously, up to 20% of cases may require endoscopic intervention. Various types of endoscopy, ranging from rigid to flexible, and equipment (Box 17.3) are available for foreign body retrieval. An overtube is available for airway protection and

frequent esophageal intubations. Retrieval should be performed within 24 hours or more urgently if the ingested object is sharp, is a disc battery, or is causing the patient pain or difficulty in handling secretions. If it is not possible to remove the object endoscopically and it is less than 2.5 cm, the object can be gently maneuvered into the stomach, from which spontaneous passage usually occurs.⁴⁹ Unsuccessful removal or obstruction requires surgical evaluation.

Esophageal narrowing is a common reason for recurrent food impaction. Narrowing may occur from benign conditions, such as peptic strictures and Schatzki's rings, or malignancy compressing the lumen. Endoscopic dilation can be performed on anatomic narrowings of the esophagus, pylorus, and anastomotic strictures. Four types of dilators are currently available: tip-weighted push bougies (Maloney or Hurst), wire-guided dilators (Savary-Gilliard or American), through-the-scope dilating balloons, and clear optical dilators that allow direct endoscopic visualization. Dilation also is indicated in patients with achalasia, although recurrence is common, and clinical efficacy is decreased with subsequent dilations.⁵⁰ In general, endoscopic dilation increases the risk of perforation, with reported rates between 0.1% and 0.4%.⁵¹

Endoscopic stenting with endoprosthesis can be performed in a wide variety of clinical scenarios. Stenting is performed for fistulas, anastomotic leaks,⁵² and malignant and nonmalignant perforations.^{53,54} In addition, malignant obstructive lesions of the esophagus, stomach, duodenum, and colon can be stented for palliation. Stents vary in size, in material (plastic or metal mesh), and by the presence or absence of a covering. Complications include increased reflux if the gastroesophageal junction is involved, bleeding, perforation, and stent migration.

Photodynamic therapy involves pretreatment of a desired target lesion with an injected photosensitizing agent, which is subsequently activated by the application of a light source. The activated photosensitizer achieves an excited state with reactive oxygen radicals that result in cellular injury.⁵⁵ In addition to high-grade dysplasia of Barrett's esophagus and esophageal cancer, photodynamic therapy has been employed for neoplasms throughout the GI tract, including the stomach, bile duct, pancreas, and colon.⁵⁶

Radiofrequency ablation of the distal esophagus has been developed as a treatment for high-grade dysplasia in Barrett's esophagus. The HALO system (Barrx Medical, Inc., Sunnyvale, CA) consists of a balloon that contains 60 separate 250- μ m electrodes circumferentially oriented on its outer surface, with electrodes separated by a distance of 250 μ m. Immediately adjacent electrodes function as bipolar devices that deliver heat to the mucosa at a controlled depth. Radiofrequency energy is delivered through the electrodes, which causes superficial tissue destruction circumferentially over a length of 3 cm. A 90-degree model allows for more focal ablation.⁵⁷

Percutaneous endoscopic gastrostomy (PEG) tube placement is a common procedure for gastroenterologists. The purpose of PEG tube placement is to improve quality of life, shorten hospitalization, prevent aspiration, improve nutritional and functional status, and prolong survival.⁵⁸ Controversy exists as to whether PEG tube placement is beneficial in patients with terminal anorexia-cachexia

syndromes or in permanent vegetative states.^{59,60} In addition to providing nutritional support, PEG placement has been used for long-term gastric decompression and recurrent gastric volvulus management. Placement is contraindicated if the anterior abdominal wall cannot be brought into contact with the anterior gastric wall, such as in morbid obesity and significant ascites. Complications, although infrequent, include wound infection, necrotizing fasciitis, peritonitis, septicemia, peristomal leakage, device dislodgement, bowel perforation, and fistula formation.⁶⁰ Possible implantation metastasis in patients with head and neck cancer also has been reported.⁶¹ Pneumoperitoneum is seen in 40% of cases, but most are asymptomatic and eventually resolve.⁶²

WIRELESS CAPSULE ENDOSCOPY

Wireless video capsule endoscopy (VCE) is a safe, noninvasive method for visualizing the entire small bowel. The capsule examination typically is performed in an ambulatory setting. Preparation involves an overnight fast. Although data are conflicting, a bowel preparation has been shown to improve visualization and result in a higher rate of capsules reaching the small intestine.^{63,64} Metoclopramide also may be beneficial in ensuring a complete small bowel evaluation before expiration of the battery life.⁶⁵ After swallowing the pill, the patient can leave the outpatient office, resume nonstrenuous daily activity, and eat 4 hours later. The data recorder is returned after 8 hours.

Common indications for VCE are evaluating obscure GI bleeding, suspected Crohn's disease, small intestinal tumors and polyps, diarrhea, malabsorption disorders, and abdominal pain.^{66,67} VCE has been shown to be superior to push enteroscopy and small bowel barium radiography in detecting sources of obscure GI bleeding.⁶⁸ Superiority also was shown when VCE was compared with double-balloon enteroscopy.⁶⁹ A major limitation of VCE is the inability to perform therapeutic interventions.

In general, VCE is a safe procedure. Contraindications for VCE include swallowing disorders, known or suspected GI obstruction, stricture, fistula, pregnancy, and possibly cardiac pacemakers or implantable defibrillators. (Although listed as a contraindication by the manufacturer, more recent studies have shown no interference with cardiac pacemakers and implantable defibrillators by VCE.^{70,71}) The capsule does not reach the cecum within recording time in 16% of cases. Abdominal x-ray study should be performed to evaluate for capsule retention, which occurs in 1.9% of all examinations, usually secondary to an anatomic abnormality, and may require endoscopic or surgical removal.^{72,73} A patency system similar in size to a video capsule, but dissolvable if retained in the body, may be useful in screening high-risk patients for possible small bowel stenosis.⁷⁴ Patients with swallowing disorders or delayed gastric emptying can have the capsule endoscopically placed into the small bowel.

A variation of the small bowel video capsule exists to evaluate the esophagus. Although similar in design to the small bowel capsule, the esophageal video capsule incorporates a camera at each end, with each camera taking 7 frames per second for a total of 14 frames per second.¹¹ Fasting time is only 2 hours, and the examination time is

less than 1 hour. The patient ingests the pill in a supine position and is gradually raised to an upright position at 2-minute intervals. The esophageal video capsule can be used to evaluate for Barrett's disease, esophageal varices, and complications of gastroesophageal reflux disease.

ENTEROSCOPY

With increasing use of wireless capsule endoscopy, the need for direct visualization and therapeutic intervention in the small bowel is growing. Until recently, deep enteroscopy had been accomplished through push enteroscopy, with or without incorporation of an overtube; through intraoperative enteroscopy performed with a surgeon's assistance during laparotomy; or through a Sonde enteroscope. These techniques are limited in that they are invasive, do not allow for examination of the entire small bowel, or do not permit therapeutic intervention to be undertaken. More recently, alternative endoscopic approaches have been developed to overcome these limitations.

Double-balloon enteroscopy uses two balloons, one at the tip of an enteroscope, and the other at the end of an overtube backloaded onto the enteroscope. Using alternating inflation and deflation of the balloons during sequential advancement of the scope and the overtube, the double-balloon enteroscope is progressively advanced through the small bowel. Utilizing both oral and anal intubation, evaluation of the entire small bowel is possible. Single-balloon enteroscopy, like double-balloon enteroscopy, incorporates a backloaded overtube with a balloon at the tip. Unlike the double-balloon enteroscope, the tip of the scope is deflected to anchor the scope against the bowel wall and permit advancement of the overtube. After advancement, the balloon on the overtube can be inflated, the intestine pleated over the overtube, and the scope advanced once again. Severe complications from double-balloon enteroscopy are described in 1% to 1.7% of patients, with pancreatitis being the most common (0.3%), and bleeding and perforation also encountered.⁷⁵ Fewer data are available regarding the complications of single-balloon enteroscopy.⁷⁶

Spiral enteroscopy was developed with the potential advantages of decreased time and increased control in examining the small bowel. The enteroscope is advanced into the small bowel by continuous rotation of the raised helix-fitted overtube, which pleats the small bowel mucosa over the overtube. An inner sleeve allows the independent motion of the overtube during advancement and withdrawal.⁷⁷ Spiral enteroscopy has demonstrated a complication rate of 0.4% with perforation found to be the leading severe complication.⁷⁶

Several studies have been performed comparing various combinations of each of the three modalities. Studies comparing single- and double-balloon enteroscopy have consistently demonstrated that double-balloon enteroscopy offers deeper penetration into the small bowel. Studies are conflicting, however, on whether there is any difference in diagnostic and therapeutic outcomes.⁷⁸⁻⁸⁰ Spiral enteroscopy offers shorter procedure time when compared to balloon-assisted enteroscopy but no apparent difference in diagnostic yield.⁸¹

COLONOSCOPY

The colonoscope is used by general practitioners, surgeons, and gastroenterologists to evaluate the colon and distal ileum. A shorter version, the flexible sigmoidoscope, is available for sigmoid examination. Colonoscopy has replaced the routine sigmoidoscopy and barium studies as the gold standard for large bowel evaluation. Indications range from colorectal screening and evaluation of anemia to therapeutic interventions such as polypectomy and palliative stenting (Box 17.4). Relative contraindications to colonoscopy are acute diverticulitis, and suspected perforation.

Before colonoscopy, the patient should be on a clear liquid diet with subsequent fasting after bowel preparation. Several bowel preparations are commercially available, including polyethylene glycol, sodium-free polyethylene glycol, low-volume polyethylene glycol with bisacodyl, and tablet sodium phosphate.⁸² Nausea, vomiting, and abdominal discomfort are common side effects among all bowel preparations. Sodium phosphate, owing to inducement of rapid volume changes, is contraindicated in patients with serum electrolyte abnormalities, advanced hepatic dysfunction, renal failure, recent myocardial infarction, unstable angina, congestive heart failure, ileus, malabsorption, and ascites.⁸² A recent meta-analysis demonstrated that the use of a split-dose polyethylene glycol for bowel preparation before colonoscopy significantly improved the number of satisfactory bowel preparations, increased patient compliance, and decreased nausea compared with the full-dose polyethylene glycol.⁸³ Inadequate bowel preparation has been attributed to failure to follow preparation instructions; later colonoscopy start time; inpatient status; procedural indication of constipation; use of tricyclic antidepressants;

Box 17.4 Indications for Colonoscopy

- Evaluation of abnormal imaging study
- Evaluation of unexplained gastrointestinal bleeding
 - Hematochezia
 - Melena
 - Presence of fecal occult blood
- Unexplained iron deficiency anemia
- Screening and surveillance for colonic neoplasia
- Chronic inflammatory bowel disease
- Clinically significant diarrhea of unexplained origin
- Intraoperative identification of a lesion not apparent at surgery (polypectomy site, location of a bleeding site)
- Treatment of bleeding from lesions such as vascular malformations, ulceration, neoplasia, and postpolypectomy site (electrocoagulation, heater probe, laser, or injection therapy)
- Foreign body removal
- Excision of polyp
- Decompression of acute megacolon or sigmoid volvulus
- Balloon dilation of stenotic lesions
- Palliative treatment of stenosing or bleeding neoplasms (laser, electrocoagulation, stenting)
- Marking a neoplasm for localization during surgery

Adapted from American Society of Gastrointestinal Endoscopy: Appropriate use of gastrointestinal endoscopy. *Gastrointest Endosc* 2012;75:1127-1131.

male gender; and history of cirrhosis, stroke, or dementia.⁸⁴ Patients undergoing flexible sigmoidoscopy usually do not require complete bowel purgation. An enema before the procedure usually is sufficient to clear the distal colon.

Complete colonoscopic examination is achieved in approximately 94% of patients.⁸⁵ Advanced age, female gender, body mass index less than 25 kg/m², diverticular disease in women, and a history of constipation or reported laxative abuse in men are predictors of a technically difficult colonoscopy.⁸⁶ In general, complications from diagnostic colonoscopy are rare. Hemorrhage and perforation occur in 0.001% to 0.008% and 0.005% to 0.14% of patients, respectively.^{87,88} Interventional procedures, such as polypectomy, can increase the risk of bleeding and perforation to 2% and 0.3%.⁸⁹ There is a theoretical risk of colonic explosion during cautery from accumulation of colonic gases, usually as a result of a carbohydrate-based bowel preparation such as mannitol.⁹⁰

Polypectomy is one of the most common interventions during colonoscopy. Pedunculated or sessile polyps may be removed with biopsy forceps, snare cautery, or argon plasma coagulation. As noted earlier, complications may be reduced with submucosal injection of saline or epinephrine.

Common causes of colonic hemorrhage include diverticulosis, postpolypectomy bleeding, vascular malformations, and hemorrhoids. Diverticular and postpolypectomy bleeding may be controlled with epinephrine injection, heater probe, electrocautery, or metallic clips. Band ligation also may be effective in hemostasis of postpolypectomy bleeds. Vascular malformations may be ablated with heater probe, electrocautery, laser, argon plasma coagulation, and metallic clips. Hemorrhoidal bleeds are effectively controlled with elastic band ligation, either with a rigid proctoscope or with a flexible video endoscope.⁹¹

Anastomotic strictures may occur from inflammatory bowel disease or postsurgical resection. These strictures can be dilated with balloon dilators or managed with self-expanding metallic stents.⁹² Endoluminal stenting may be used as palliation or as a bridge to surgery for near obstructive malignant lesions.⁹³ Laser therapy is another option for tumor ablation.⁹⁴

Colonic decompression and placement of temporary rectal tubes is indicated in patients with sigmoid or cecal volvulus and acute pseudo-obstruction. Foreign objects also may be removed endoscopically.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

ERCP is used to evaluate and treat diseases of the pancreas, bile ducts, gallbladder, and liver. With the advent of highly diagnostic alternative modalities, such as magnetic resonance imaging and EUS, the role of ERCP has slowly evolved into a therapeutic rather than diagnostic tool (Box 17.5).⁹⁵ The procedure is performed under anesthesia with the patient lying on the left side or prone. Significant coagulopathy should be corrected if sphincterotomy is to be performed. Antibiotic prophylaxis is indicated in patients undergoing ERCP for suspected biliary obstruction where incomplete drainage is anticipated or in patients with sterile pancreatic fluid collections that communicate with the

Box 17.5 Indications for Endoscopic Retrograde Cholangiopancreatography

- Treatment of choledocholithiasis
- Treatment of biliary pancreatitis
- Evaluation and treatment of recurrent pancreatitis
- Evaluation and treatment of ascending cholangitis
- Tissue sampling of suspected biliary and pancreatic malignancies
- Diagnosis of ampullary tumors
- Malignant and benign biliary stricture management (sphincterotomy, dilation, stent placement)
- Photodynamic therapy
- Diagnosis and treatment of biliary and pancreatic duct injury and leak
- Pancreatic pseudocyst (stent)
- Stent removal
- Biliary manometry
- Endoscopic sphincterotomy in type I sphincter of Oddi dysfunction
- Endoscopic sphincterotomy in type II sphincter of Oddi dysfunction with manometry-confirmed pressure >40 mm Hg

Adapted from Adler DG, Baron TH, Davila RE, et al: ASGE guideline: The role of ERCP in diseases of the biliary tract and pancreas. *Gastrointest Endosc* 2005;62:1-8.

pancreatic duct. Patients undergoing EUS with aspiration of a cystic lesion along the GI tract and patients undergoing percutaneous feeding tube placement are also recommended to receive antibiotic prophylaxis.⁹⁶ Glucagon may be beneficial to reduce peristalsis of the small bowel, facilitating cannulation of the bile duct. Secretin may be administered to assist in identification of the papilla of Vater in the setting of ulceration, scarring, or malignancy, or the minor papilla in cases of pancreas divisum.

After oral intubation, the side-viewing duodenoscope is advanced into the second portion of the duodenum, where the papilla of Vater is located, and the papilla is subsequently cannulated. Visualization of the common bile duct or pancreatic duct is achieved with injection of contrast dye and radiographic fluoroscopy. Biliary obstruction, usually secondary to choledocholithiasis, may be treated with ERCP. Stone extraction is successful in 90% of cases.⁹⁷ Techniques for stone extraction involve biliary sphincterotomy or balloon sphincteroplasty, followed by stone removal by soft balloon or wire basket. Large stones may be fragmented before removal with mechanical, laser, or electrohydraulic lithotripsy. Inadequate bile drainage may require biliary stenting to prevent ascending cholangitis.

Bile duct stenting is used to alleviate obstruction caused by malignant and benign disorders and to treat bile duct injuries and leaks.⁹⁸ Pancreatic stents are used for pancreatic duct disruptions⁹⁹ and pseudocysts that communicate with the pancreatic duct.¹⁰⁰ Stents vary in diameter, length, material (plastic, metallic, and biodegradable), and occlusion rates.

Malignant and benign strictures may be dilated with hydrostatic balloons. ERCP also is used to obtain brush cytology, fine-needle aspiration, or biopsy specimens of a

suspected malignancy. Sensitivity is typically low, ranging from 30% with brushings to 60% with all three methods combined.¹⁰¹ Reports of photodynamic therapy for non-resectable cholangiocarcinoma have been described.¹⁰² Manometry, the measurement of biliary and pancreatic sphincter pressures, may be used to evaluate sphincter of Oddi dysfunction, postcholecystectomy pain, and idiopathic pancreatitis.

Choledochoscopes and pancreatoscopes are small endoscopes that can be passed through a duodenoscope channel port into the common bile duct or pancreatic duct. This placement allows direct visualization of the duct lumen. Direct visualization of vasculature within a biliary stricture may help differentiate benign from malignant lesions.¹⁰³

ERCP carries a substantial morbidity risk. Pancreatitis is the most common complication, occurring in 7% of cases.¹⁰⁴ Although the benefits of prophylactic administration of gabexate mesylate are controversial,^{105,106} pancreatic stenting of high-risk patients seems to be efficacious.¹⁰⁷ Stenting decreases papillary hindrance to pancreatic duct drainage. Other reported complications include hemorrhage, cholangitis, and perforation.¹⁰⁸

ENDOSCOPIC ULTRASOUND

EUS, a combination of endoscopy and ultrasonography, is used for evaluation of luminal walls and structures adjacent to the GI tract. Dedicated ultrasound endoscopes with linear or radial viewing can be used. In addition, high-frequency ultrasound probes that can be passed through the channel port of standard endoscopes are commercially available.¹⁰⁹

A common application of EUS is to evaluate benign and malignant mucosal and submucosal lesions. EUS is employed routinely for detection and staging of esophageal, gastric, ampullary, pancreaticobiliary, colorectal, and lung neoplasms. EUS also is used to evaluate chronic pancreatitis and biliary disorders, such as calculi. In general, EUS is an extremely sensitive tool and is often superior to computed tomography or magnetic resonance imaging for diagnosis and staging of neoplasia.¹¹⁰ An advantage of EUS over these noninvasive modalities is the ability to perform therapeutic interventions when needed. Fine-needle aspiration can be done with EUS, which also can be used for pseudocyst drainage, celiac plexus blocks, cholangiography, pancreatography, and tumor ablation.¹¹¹

Preparation of the patient is similar to that for standard endoscopy. Complications from instrumentation vary, depending on the clinical scenario. Perforation rates, usually cervical esophageal in origin, occur in 0.03%.¹¹² Despite the low risk of bacteremia after EUS fine-needle aspiration, prophylactic antibiotics are recommended for pancreatic cystic lesions and perhaps the perirectal space. Pancreatitis, hemorrhage, and bile peritonitis also have been reported.¹¹³

ENDOSCOPY IN THE PREGNANT PATIENT

Endoscopy in the general population is commonplace and widely regarded as safe. Endoscopy during pregnancy,

however, raises the unique concern of fetal safety and is generally avoided when possible. Potential risks of endoscopy include teratogenesis or premature induction of labor from medications, hypoxemia, and hemodynamic fluctuations, all of which could cause fetal harm. Also, a lack of quality research into the safety of these procedures during pregnancy adds to the uncertainty of performing endoscopic procedures in this population.¹¹⁴

In controlled studies, no differences were seen between pregnant and nonpregnant patients undergoing EGD¹¹⁵ or in fetal outcomes regardless of a history of EGD during pregnancy.¹¹⁶ Gross acute upper GI bleeding, dysphagia associated with involuntary weight loss, and suspected GI mass have all been suggested as acceptable indications for EGD in the pregnant patient. Data surrounding colonoscopy during pregnancy are less robust, limited to small studies, case series, and case reports, and therefore accurate estimation of risk is not possible. Colonoscopy should be considered for unknown colonic mass or stricture, severe uncontrolled colonic hemorrhage, as an alternative to surgery in colonic pseudo-obstruction, and when required before colonic surgery.¹¹⁴

ERCP is associated with unique risks that must be appreciated when considering performing the procedure on a pregnant patient. Procedural time is often longer and increased doses of anesthetic medications are required as compared to EGD. ERCP also places the patient at risk for postprocedural complications including bleeding and perforation from sphincterotomy and post-ERCP pancreatitis. ERCP during pregnancy also introduces a theoretical risk from fetal radiation exposure during fluoroscopy. Despite these risks, it is felt that ERCP can safely be performed during pregnancy as the literature has consistently demonstrated a high maternal success rate, a low procedural complication rate, and generally favorable fetal outcomes.¹¹⁴ Additionally, although estimates of fetal radiation exposure vary, with careful technique, doses of radiation can be limited to less than the 5 rad threshold often used to minimize risk of fetal anomalies or pregnancy loss.¹¹⁷ Indications for ERCP during pregnancy include choledocholithiasis with obstructive jaundice, ascending cholangitis, or gallstone pancreatitis, or in the presence of biliary or pancreatic ductal injury.¹¹⁴

When considering GI endoscopy in the pregnant patient the physician must ultimately weigh the risks of performing the procedure to the fetus against the benefits to the mother. Guidelines exist offering suggestions to help minimize these risks, such as limiting procedures to patients with strong indications, choosing medications that are safe during pregnancy, close involvement of obstetric staff, and performance of the procedure by an experienced endoscopist. In situations in which therapeutic intervention is necessary, endoscopy may offer a safe alternative to surgery.¹¹⁸

KEY POINTS

- Endoscopy serves a diagnostic and a therapeutic role in the management of patients.
- Informed consent must be obtained before any elective endoscopic procedure.

Continued on following page

KEY POINTS (Continued)

- Perforation and bleeding are the major complications of endoscopy. Although standard endoscopy is generally low risk, interventional procedures increase the rate of complications. A benefit versus risk analysis must be done before any procedure.
- Cardiopulmonary decompensation is a possible complication of anesthesia.
- Endoscopy is the most effective technique to identify and control GI hemorrhage.
- Endoscopy plays a crucial role in the palliative care of patients with GI tract malignancy.
- ERCP has evolved into a therapeutic tool for treating pancreaticobiliary disease.
- Endoscopy in the pregnant patient can be done safely but should be limited to patients with strong indications.

SUMMARY

Acute kidney injury (AKI) is common and serious. The incidence of AKI in hospitalized patients ranges from 5% to 7% and is rising rapidly.¹⁻⁴ In a multinational study of critically ill patients, the prevalence of AKI requiring dialysis was 5.7% with a mortality rate of 60.3%.⁵ In addition, patients with AKI have a higher risk for developing other nonrenal comorbid conditions,⁶ and when present in conjunction with other conditions, AKI is associated with higher mortality rate.⁷⁻⁹ The use of renal replacement therapy (RRT) for treatment of AKI has been ongoing over the last 60 years.¹⁰ According to Hoste and Schurgers, 200 to 300 patients per 1 million population per year develop AKI and are treated with RRT.¹¹ Despite this, these patients still have a mortality rate of 50% to 60%.¹¹ Advances and optimization of RRT could benefit the high mortality rate associated with AKI.

The establishment of continuous renal replacement therapy (cRRT) evolved as a treatment for the hemodynamically unstable patient unable to undergo standard intermittent hemodialysis (IHD). Although world trends for cRRT use show an increase in utilization, the majority of the world continues to treat AKI with IHD.¹² Although cRRT offers many theoretical advantages such as better fluid balance, hemodynamic management, and renal recovery, the superiority of cRRT over IHD for RRT in the intensive care unit (ICU) remains controversial.¹³

This chapter first reviews the physiologic principles behind the multifaceted aspect of cRRT before moving onto

the technical aspects and clinical issues. We also discuss possible technical complications and ethical considerations in the use of cRRT.

PHYSIOLOGIC PRINCIPLES

Dialysis uses a semipermeable membrane to alter the molecular composition and concentration of blood to restore the body back toward homeostatic balance. Blood flows along one side of the semipermeable membrane and a wash solution, dialysate, flows on the opposite side of the membrane (Fig. 18.1). Dialysis relies upon two physical forces—*diffusion* and *convection*—either in isolation or in combination (Fig. 18.2). In *diffusion*, the net movement of solute is directly dependent on the diffusivity of the solute and solvent, permeability of the membrane, surface area across the membrane, and concentration gradient. Other membrane characteristics also play a role: thickness, pore size, and electrostatic charge. In order to maximize the concentration gradient between the blood and dialysate, the dialysate runs countercurrent to the flow of blood. Any substance that is in higher concentration in the blood than the dialysate flows “down” its concentration gradient and leaves the blood and flows into the dialysate. Conversely, any solute that is in higher concentration in the dialysate (e.g., bicarbonate) will leave the dialysate, cross the semipermeable

HEMODIALYSIS

Indications

- Metabolic acidosis that is refractory to medical treatment
- Electrolyte abnormalities, such as hyperkalemia, that are refractory to medical treatment
- Intoxication with dialysable drugs (e.g., salicylates, lithium)
- Volume overload that is refractory to diuretics
- Uremia and its complications (encephalopathy, pericarditis, bleeding)

In patients with chronic kidney disease:

- Glomerular filtration rate 10–15 mL/min/1.73m²
- Weight loss, anorexia, loss of appetite
- Any of the sequelae of impaired renal function listed above

Figure 18.1 Hemodialysis and the filter at a microscopic level. Netter illustration from www.netterimages.com @ Elsevier Inc. All rights reserved. (Netter Plate 10-9 Membrane and Dialysis).

membrane, and enter the blood. The movement of molecules down their concentration gradient from one solution to another continues until equilibrium is achieved in both the blood and dialysate. Diffusion is more efficient in the clearance of small-molecular-weight substances (less than

Figure 18.2 Diffusion and convection are schematically represented. During diffusion, the solute flux (J_x) is a function of the solute concentration gradient (dc) between the two sides of the semipermeable membrane, the temperature (T), the diffusivity coefficient (D), the membrane thickness (dx), and the surface area (A), according to the following equation: $J_x = DTA (dc/dx)$. Convective flux of solute (J_f) requires instead a pressure gradient between the two sides of the membrane (transmembrane pressure, or TMP), which moves a fluid (plasma water) with its crystalloid content in a process called ultrafiltration (which is also dependent on the membrane permeability coefficient, or K_f). Colloids and cells will not cross the semipermeable membrane, depending on the pores' size. $J_f = K_f \times \text{TMP}$ and $\text{TMP} = P_b - P_d - \pi$ where P_b is the blood hydrostatic pressure, P_d is the hydrostatic pressure on the ultrafiltrate side of the membrane, and π is the oncotic pressure. From Ronco, C. In *Critical Care Nephrology*, 2/E. Phila., WB Saunders, 2008. (Fig. 210-001).

500 daltons [D]). This is particularly useful in correcting the imbalance in small molecule electrolytes (e.g., K, Ca, Mg, PO_4) (see Fig. 18.1). Thus, thoughtful manipulation of dialysate allows the clinician to decide what will be removed from the blood and what will be added to the blood during a dialysis session.

In convection, solutes move across a membrane in response to or following solvent flux or drag; solutes are moving along with the solvent containing them (Fig. 18.3). This is similar to a wave pushing seashells onto the shore. *Solvent drag* is limited only by the pore size or electrostatic charge of any semipermeable membrane that is applied across the passage of the solution. In convection, the concentration of a solute is similar on either side of the membrane. Convection is more efficient at the clearance of large-molecular-weight substances (500-5000 D). Convective removal of plasma water from blood across a large-pore, semipermeable membrane results in an *ultrafiltrate* with a solute composition equivalent to plasma water.

Fluid removal is termed *ultrafiltration* (UF). UF utilizes hydrostatic pressure, which is applied across a semipermeable membrane. This is a form of convective removal of solute. The clearance of molecules in UF is dependent on the volume of fluid removed. It may be applied in isolation (in volumes usually <5 L/day) or in combination with other blood clearance techniques, such as dialysis. Table 18.1 reviews the commonly used terms in cRRT.

One other form of clearance of the blood is through a process called *adsorption*. This refers to molecules in the blood sticking or adhering to the semipermeable membrane. This process is dependent on the molecules contained in the blood and the composition of the semipermeable membrane. Adsorption is usually time dependent (i.e., as

Figure 18.3 Diffusion is the result of microscopic molecular movements. **A**, Convection without diffusion moves all molecules equally and does not result in separation. **B**, Unhindered ordinary diffusion causes initially separated molecules to move together. **C**, Forced diffusion, provided by an external force, separates molecules when the force acts differently on different molecular types. From Ronco, C. In *Critical Care Nephrology*, 2/E. Phila., WB Saunders, 2008. (Fig. 209-001).

Table 18.1 Modalities of Continuous Renal Replacement Therapy (cRRT)

Feature	SCUF	CVVH	CVVHD	CVVHDF
Method of clearance	Convection	Convection	Diffusion	Convection and diffusion
Middle molecular size clearance	+	+++	+	+++
Replacement fluid	None	Present	None	Present
Dialysate	None	None	Present	Present
Effluent composition	Ultrafiltrate	Ultrafiltrate	Dialysate + ultrafiltrate	Dialysate + ultrafiltrate

CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis; CVVHDF, continuous venovenous hemodiafiltration; SCUF, slow continuous ultrafiltration.

the semipermeable membrane is used over time, it will become saturated with a given molecule). The process begins anew when the membrane is changed (approximately every 72 hours). Some inflammatory cytokine clearance occurs through this process.¹⁴

MODALITIES

The various modalities of cRRT are depicted in Table 18.1 and Figure 18.4.

When UF only is employed on a continuous basis, this is termed slow continuous ultrafiltration (SCUF). This modality would be considered in patients with volume overload, for example, in congestive heart failure (CHF) or anasarca from nephrotic syndrome or liver disease.

Dialysis may also be performed on an intermittent basis (IHD or sustained low-efficiency dialysis [SLED]) (see Fig. 18.1) or a continuous basis (Figs. 18.4 and 18.5). When performed continuously, this is known as continuous venovenous hemodialysis (CVVHD). The “venovenous” refers to the access employed and will be discussed in a later section.

Figure 18.4 Schematic representation of the most common continuous renal replacement therapy (RRT) setups. **A**, Slow continuous ultrafiltration (SCUF). **B**, Continuous venovenous hemofiltration (CVVH). **C**, Continuous venovenous hemodialysis (CVVHD). **D**, Continuous venovenous hemodiafiltration (CVVHDF). See text for specifications. Dark triangles represent blood flow direction; light triangles indicate the flow of dialysate/replacement solutions. Di, dialysate in; Do, dialysate out; P, pump; Q_b , blood flow; Q_d , dialysate solution flow; Q_f , replacement solution flow; Q_{uf} , ultrafiltration flow; Rpost, replacement solution postfilter; Rpre, replacement solution prefilter; Uf, ultrafiltration; V, vein. From Ronco, C. In *Critical Care Nephrology*, 2/E. Phila., WB Saunders, 2008. (Fig. 210-002).

Figure 18.5 Schematic representation of different renal replacement modalities: hemodialysis, hemofiltration, and hemodiafiltration. From Ronco, C. In *Critical Care Nephrology*, 2/E. Phila., WB Saunders, 2008. (Fig. 215-001).

As described earlier, this is a diffusion-based process that primarily provides small molecule clearance.

Hemofiltration (HF) relies on convective removal of plasma solute, in high fluid volumes, across a semipermeable membrane (see Fig. 18.5). Hydrostatic pressure is applied across the semipermeable membrane as a positive pressure on the blood side of the membrane or a negative pressure on the fluid collection side, or both. Fluid lost through this process is restored with replacement fluid in either a predilutional mode (before the filter containing the semipermeable membrane) or in a postdilutional mode (after the filter). The composition of the effluent fluid created by this system of plasma water exchange (*hemofiltrate*) depends on the membrane *sieving coefficient* for that particular solute and that particular semipermeable membrane. The sieving coefficient is expressed in terms of the ratio of the solute concentrations of the hemofiltrate to the plasma and is a function of membrane thickness, pore size, and electrostatic charge (Fig. 18.6). Hemofiltration is more efficient in middle-molecular-weight compound clearance, but less so for smaller solutes. When performed on a continuous basis, this is known as continuous venovenous hemofiltration (CVVH).

Finally, *hemodiafiltration* (HDF) combines both diffusive and convective solute removal (see Fig. 18.5). When performed continuously, this is known as continuous venovenous hemodiafiltration (CVVHDF). Dialysate is used in this configuration and runs countercurrent to the blood.

Figure 18.6 In vivo measured sieving coefficients for various serum contents during hemofiltration with a noncuprophane membrane. From Ronco, C. In *Critical Care Nephrology*, 2/E. Phila., WB Saunders, 2008. (Fig. 019-001).

Concurrently, replacement solution is infused either prefilter or postfilter. This allows for both efficient low-molecular-weight and enhanced middle-molecular-weight clearances. This modality has been employed for sepsis and multiorgan failure, in which removal of cytokine mediator substances is thought to be important.¹⁵

Figure 18.4 illustrates the mechanics of each of these modalities. Any modality may be described according to its frequency (I [intermittent] versus C [continuous]) and technique (H or HF [hemofiltration], HD, HDF, or UF) as shown in Table 18.2. To date, no one modality has been shown to be superior to the others. Continuous techniques are additionally described according to their vascular access: arteriovenous (AV) or venovenous (VV) (see later discussion under “Access”). Much debate has occurred regarding the superiority of intermittent therapies versus the continuous therapies. To date, the continuous therapies have not been shown to be superior in clinical outcomes to the intermittent therapies. Although the intermittent therapies (IHD and SLED) may be less costly, the continuous modalities allow for hemodynamic stability, enhanced fluid removal, and delivered dose of dialysis.¹⁶

PRINCIPLES OF ULTRAFILTRATION

Achieving fluid balance by removal is the most frequently requested application for dialytic intervention and is considered the simplest form of continuous therapy. Fluid is drawn from the blood space across a semipermeable membrane. The fluid removed, or ultrafiltrate, has the characteristics of plasma water. With knowledge of the sieving coefficients of a particular membrane for various solutes, the ultrafiltrate can be used to determine the composition of serum and can help avoid an excessive number of blood draws.

In prescribing UF, a specific volume of fluid loss should be determined, with the UF rate (Q_{UF}) set to achieve that loss over a set time frame. It cannot be overemphasized that this form of therapy is by nature *slow*. The steady, constant loss of fluid at a rate that does not exceed the plasma-refilling rate gives this form of therapy its hemodynamic stability. If extremely rapid UF in a short time frame is the therapeutic intent, intermittent forms of pump-driven UF are more efficient and therefore the treatment of choice.

The artificial membranes usually employed have a high UF coefficient (K_{UF}), allowing water to pass quite freely. Any pressure difference between the blood side and the ultrafiltrate side of the filter results in fluid passage. Higher pressures in the blood compartment of the filter result in net fluid flow from the blood to the ultrafiltrate compartment. This flow is enhanced by applying negative pressures to the ultrafiltrate compartment through gravity or by pumped mechanical suction. This pressure should be held constant and not be subject to rapid variations. If transmembrane pressures are too high, membrane rupture and blood loss may result.

Common UF rates range from 100 to 400 mL/hour. Larger amounts may be obtained if there is a need for rapid fluid removal. Automated continuous machines control UF through a volume-driven system, establishing a fixed loss of a determined amount of fluid from the system over a given time period (usually on an hourly basis).

Table 18.2 Commonly Used Forms of Extracorporeal Renal Replacement Therapy

Therapy	Definition	Use	Specific Techniques
Ultrafiltration	Plasma water removal, usually <5 L/d	Fluid overload High delivery in CRF AKI CHF	SCUF CVVUF IUF
Hemodialysis	Diffusion-based process using dialysate and semipermeable membrane	Azotemia Acid-base disturbance Electrolyte balance Volume control	CVVHD IHD SLED
Hemofiltration	Convection-based process using plasma water exchange methods across semipermeable membrane	Azotemia Acid-base disturbance Electrolyte balance Volume control Cytokine removal ARDS, AKI, CHF, MOF	CVVH IH
Hemodiafiltration	Combining diffusion and convection (10-L exchanges) for small and middle molecular loss	Azotemia Volume control Cytokine removal ARDS, AKI, CHF, MOF	CVVHDF IHDF

AKI, acute kidney injury; ARDS, acute respiratory distress syndrome; ARF, acute renal failure; CHF, congestive heart failure; CRF, chronic renal failure; CVVH, continuous venovenous hemofiltration; CVVHDF, continuous venovenous hemodiafiltration; CVVUF, continuous venovenous ultrafiltration; IH, intermittent hemofiltration; IHD, intermittent hemodialysis; IHDF, intermittent hemodiafiltration; IUF, intermittent ultrafiltration; MOF, multiple organ failure; SCUF, slow continuous ultrafiltration; SLED, sustained low-efficiency dialysis.

The blood flow rate (Q_b) has a significant effect on any UF system. During UF, plasma water is removed from the blood as it moves through the dialysis filter, thereby increasing the viscosity of blood in the filter. If the viscosity increases excessively, the system will clot. Therefore, whenever UF is being prescribed, an appropriate Q_b must be prescribed in order to accommodate the prescribed UF.

Careful attention should be given to the amount of access recirculation. Rates greater than 15% are associated with a greater incidence of clotting. This tendency is more evident at higher UF rates (>300 mL/hour), at which the returning blood tends to have a higher hematocrit, creating a more viscous, afferent blood flow.

PRINCIPLES OF HEMOFILTRATION

As more fluid removal is performed, additional fluid may be needed to replace that which is lost. This is termed hemofiltration or plasma water exchange. Fluid replacement can be delivered into the blood circuit either prefilter, before UF has occurred (predilutional hemofiltration), or after fluid has been removed by the filter (postdilutional hemofiltration).

In predilutional hemofiltration, ultrafiltrated fluid reflects the mixture of blood and replacement solution. To use ultrafiltrate as a surrogate for blood sampling (see previous discussion) would be problematic because correction has to be made for the degree of dilution and for the electrolytic composition of the replacement fluid. Because the oncotic pressure of blood is reduced within the filter, a greater rate of fluid removal is possible at the same transmembrane hydrostatic pressure. This increased rate of fluid removal is offset by dilution of plasma solute. In other

words, the overall mass transfer of uremic toxins is reduced, and higher rates of fluid exchange are required to compensate. It is common to have exchange rates of 30 to 40 L/day. Predilutional hemofiltration may also be used for patients with high hematocrit levels in an effort to reduce clotting episodes.

Postdilutional fluid replacement has the advantage of being easier to perform, with lower rates of fluid exchange compared with the predilutional system. One problem with this form of replacement is the increased oncotic pressures at the venous end of the filter. With high rates of exchange or high degrees of access recirculation, blood viscosity may be increased to the extent that clotting may occur. Therefore, fluid exchange rates may be dictated by such factors as hematocrit, blood flow, and access recirculation. Table 18.3 compares predilutional and postdilutional CVVH.

The end point of hemofiltrative therapy is determined by the balance between solutes removed with the ultrafiltrate and those replaced with the substitution fluid. A blood pump is used to increase blood flow and allow higher filtration rates. Infusion pumps are used for the delivery of replacement solution.

The system should be kept below a filtration fraction of 15% in postdilution and 30% in predilution hemofiltration for efficient operation and a lower risk of clotting.

PRINCIPLES OF HEMODIALYSIS

In hemodialysis (HD), the flow of dialysate is countercurrent to that of blood to maximize transmembrane concentration differences across all blood concentrations and at all levels of the filter. Blood flow (100 to 300 mL per minute)

Table 18.3 Comparison of Pre- and Postdilution Techniques for Continuous Venovenous Hemodiafiltration/Hemofiltration

Feature	Predilution	Postdilution
Clearance	Less clearance per milliliter	High small solute clearance per milliliter
Efficiency	Reduced efficiency by 10-15% and reduced filtration fraction	
Ultrafiltration rate limitations	Ultrafiltration rate not limited	Ultrafiltration rate limited by blood pressure and hemoconcentration
Blood viscosity	Low viscosity of the blood	High viscosity of the blood and increased risk of clotting

is maintained well above the usual dialysate flow rates (15 to 30 mL per minute). By contrast, in IHD, blood, rather than dialysate flow, is the limiting factor in diffusive clearance. Clearance of low-molecular-weight substances (e.g., urea, creatinine) is “flow-dependent” because there is little resistance to transmembrane movement posed by the porous membrane. Substances of larger molecular weight (e.g., β_2 -microglobulin, vitamin B₁₂) are relatively slow in crossing the dialyzer membrane and are “membrane-dependent” molecules. Using the high-flux membrane characteristics generally employed with continuous therapies, substances with molecular weights (masses) of 20,000 to 30,000 D are transferred at rates that have an inverse relationship to their molecular weights.

Electrolytes, urea, and creatinine easily cross membranes at a rate that is directly proportional to membrane surface area, temperature, and concentration difference, and inversely proportional to viscosity, distance from the membrane, and molecular size. Changing the concentration of various elements in the dialysate alters solute balance. Balance is achieved, however, only between transferable particles. Protein-bound solutes are not subject to the concentration gradients that drive the molecular transport across the membrane. This concept is the basis for altered drug kinetics when patients are subjected to continuous supportive therapy.

In CVVHD, dialysate flow rates remain the most influential factor in determining urea clearance.¹⁷ Dialysate usually is delivered via pumps at rates of 15 to 40 mL per minute. Given adequate blood flow through the circuit, one can see why the limiting factor for flow-dependent transfer is the relatively low dialysate flow rate. Blood flow and filter membrane have limited effects on the diffusion of molecules compared with the potential of dialysate flow changes.

In addition to the dialysate inflow, the dialysate outflow also must be controlled. By setting the outflow rate higher than dialysate inflow rates, one can create a negative transmembrane pressure promoting UF across the dialysis membrane. This difference in flow is used to establish the rate of UF. An increase or decrease in this flow difference would increase or decrease the rate of fluid loss. Dialysate flow is external to and independent of blood flow, and therefore, one may see continued dialysate flow in a system with virtually no blood flow. Although decreases in hemofiltration flow rates may indicate system clotting, dialysate flow rate changes have no predictive value for clotting and may continue despite blood-side occlusion.

Table 18.4 Clinical Considerations in Continuous versus Intermittent Renal Support in the Intensive Care Unit

Condition/Feature	Method of Delivery	
	Intermittent	Continuous
Hemodynamic instability	No/yes	Yes
High fluid requirements	No/yes	Yes
High potassium generation	Yes	No
High catabolism	Yes	Yes/no

Box 18.1 Nonrenal Indications for Continuous Renal Replacement Therapy (cRRT)

Lactic acidosis - with ongoing production
 Crush injury - Myoglobin removal
 Tumor lysis syndrome
 Temperature control
 Massive volume overload
 High ammonia
 Removal of toxins with high intracellular concentrations (e.g., Li+)
 Maintenance of cerebral perfusion pressure (CPP) (suggested by some evidence)

CONTINUOUS RENAL REPLACEMENT THERAPY VERSUS INTERMITTENT THERAPY

The clinical presentation and circumstances may favor either intermittent or continuous therapies (Table 18.4). There are many theoretical benefits that may favor the use of cRRT over intermittent forms of therapy, such as improved hemodynamic stability, faster resolution of fluid overload, and increased dialysis dose delivery (Table 18.5). Box 18.1 lists some nonrenal indications for using cRRT. However,

Table 18.5 Intermittent and Continuous Forms of Renal Replacement Therapy

Feature	Modality		
	IHD	SLED	cRRT
Setting	Hemodynamically stable	Hemodynamically unstable	Hemodynamically unstable Increased intracranial pressure
Advantages	Rapid removal of low-molecular-weight substances and toxins	Hemodynamic stability	Easy control of fluid balance
	Time when not receiving treatment may be used for diagnostic or therapeutic procedures	Time when not receiving treatment may be used for diagnostic or therapeutic procedures	Hemodynamic stability
	Reduced anticoagulation exposure	Decreased anticoagulation requirements	Continuous removal of toxins
Disadvantages	Low cost	Slower clearance of toxins	Slower clearance of toxins
	Hypotension with rapid fluid removal	Technically complex	May require anticoagulation
	Dialysis disequilibrium with risk of cerebral edema		Patient immobilization
	Technically complex		Hypothermia
			Increased costs

cRRT, continuous renal replacement therapy; IHD, intermittent hemodialysis; SLED, sustained low-efficiency hemodialysis.

Box 18.2 Disadvantages of Continuous Renal Replacement Therapy (cRRT)

Anticoagulation
No rapid removal of electrolytes
Limited role in overdose
Hypothermia (masks a true fever)
Electrolyte depletion: K^+ , PO_4^{3-} , Ca^{2+} , Mg^{2+}
Bleeding and thrombosis complications
Minimal removal of protein-bound substances
Membrane adsorption
Negative balance of selenium, copper, thiamine, Mg^{2+} , Ca^{2+}

clinical trials demonstrating an evidence-based assessment of these potential advantages are still lacking.

Hemodynamic stability is one of the most important advantages for the use of cRRT over intermittent modalities. Slower removal of solute and fluid from the intravascular space by continuous techniques should allow adequate time for refilling from the interstitium and intracellular space, theoretically minimizing therapy-induced hypotension. There are longer term implications for renal recovery, with IHD-related hemodynamic instability potentially predisposing to recurrent renal injury. The data from rigorous, comparative studies seem to lead to varying conclusions, however.

Continuous therapies are able to deliver a higher dose of clearance compared to intermittent therapies. The concept of dose will be covered later in this chapter. Intermittent therapy may have to be provided at a high frequency to produce equivalent levels of solute removal.

Definitive data to support many of the suspected advantages of cRRT are still lacking. In fact, Box 18.2 lists some of the disadvantages of cRRT. Interpretation of much of the published data has been hampered by retrospective analysis,

the use of historical control groups, incomplete randomization, incomplete descriptions of patient populations and dialysis dose delivery, and study group–control group heterogeneity.

In the absence of a solid evidence base, how should one decide between prescribing continuous or intermittent therapy? The basic indications for delivering renal support remain unchanged (Box 18.3) and range from the most frequent request for fluid balance to more esoteric requirements such as toxin removal. Common considerations in choosing to apply intermittent or continuous support are listed in Table 18.3, being mindful of numerous relative advantages and disadvantages of each (see Table 18.5).

Hybrid therapies that combine cRRT and IHD techniques are described in the literature as extended daily dialysis,

SLED, or prolonged daily intermittent RRT. These therapies use standard IHD equipment to apply lower solute clearances and UF rates for prolonged periods and aim to combine the desirable features of each modality—reduced rate of UF for improved hemodynamic stability, low efficiency solute removal to minimize solute disequilibrium, longer treatment duration to achieve prescribed dialysis dose, and intermittency for the convenience of diagnostic and therapeutic procedures during scheduled downtime.

Sustained low-efficiency dialysis is typically performed with low blood flows of about 200 mL per minute and dialysate flows of 100 to 300 mL per minute. Clearance is predominantly diffusive; however, available systems may also combine diffusive and convective clearance via HDF. Overall, hybrid therapy provides a high dose of dialysis with minimal urea disequilibrium and good control of electrolytes, with survival similar to that predicted by a variety of illness severity scores.

CONTINUOUS HEMODIALYSIS VERSUS CONTINUOUS HEMOFILTRATION

Deciding between the forms of dialytic therapy is dependent on a number of factors: rate of catabolism, mean arterial pressure with resultant blood flow rates, UF rates required or desired, and access choice. The patient's primary diagnosis also influences which modality is chosen, as some data suggest an improved outcome with the use of hemofiltration in some patients with multiple organ failure. Therapy effect on such vastly differing substances as urea and creatinine, molecules of “middle” molecular weight (β_2 -microglobulin, vitamin B₁₂), cytokines (tumor necrosis factor- α , interleukins), and hormones (endothelin, angiotensin) is the subject of intense research on potential differences in therapy choice and its influence on patient outcome.

Assuming a flawless period of therapy delivered by all modalities, urea clearance would have a great influence on therapy choice. Circuit variations, anticoagulation, “downtime” of the differing techniques, clotting frequency, and blood and dialysate flow rates all should be considered in the choice. Interruptions to therapy decrease overall treatment effectiveness.

Blood urea nitrogen and creatinine are frequently used as indicators of the need for renal support. Urea or creatinine appearance rates can be used as a gauge of the *quantity* of therapy required. Patients with high urea generation rates should receive HD. The only influence on urea removal in hemofiltration is fluid *exchange* rates; the increased need for fluid removal carries with it a need for greater differences in fluid exchanges, limiting the replacement volume. Given a maximal UF rate dictated by the system's blood flow rate (maximal filtration fraction) and by the patient's hematocrit level, solute clearances are restricted and may be inadequate for that particular patient's needs. Selection of HD allows for the UF rates needed without compromising solute clearance because dialysate flow rates are generally not as limited.

The influence of the dialysate rate on dialyzer clearance is depicted in Figure 18.7. The higher the rate, the more effective the urea clearance, until one reaches a rate approximating the effective plasma flow of the system. The stability of continuous therapies lies in their low rates of exchange

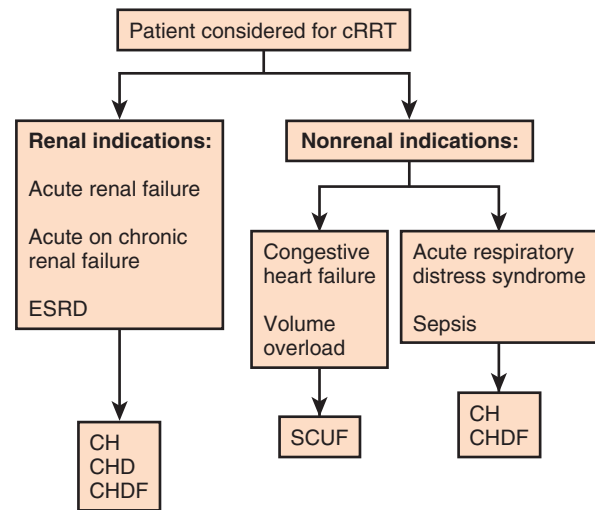

Figure 18.7 Algorithm for the choice of modality in continuous renal replacement therapy (cRRT). CH, continuous hemofiltration; CHD, continuous hemodialysis; CHDF, continuous hemodiafiltration; ESRD, end-stage renal disease; SCUF, slow continuous ultrafiltration. From Ronco, C. In *Critical Care Nephrology*, 2/E. Phila., WB Saunders, 2008. (Fig. 019-008).

over a longer period. The increase in clearance rates must be balanced against the desire to provide stable therapy. If one desires a high rate of removal in a short time, then an intermittent therapy should be employed.

A drawback to diffusive methods of delivery is the relatively low removal rates of the higher-molecular-weight substances. As noted earlier, convection provides greater clearance for substances 5000 to 20,000 D. HD may have limitations when the goal of therapy is targeted toward these larger molecules. This may be the basis for the early reports of improved outcome with patients who were subjected to HDF techniques. The suggested advantage comes from the removal of cytokines and the influence on endotoxin adsorption.

Figure 18.7 depicts an approach to determining the modality of cRRT based on the patient presentation.

PRESCRIPTION VARIABLES

DOSE

Dose in RRT refers to how much of a measure of the quantity of a representative marker solute is removed from a patient. The concept of dose is used to gauge the adequacy of a given treatment. Urea clearance has been the standard molecular marker for IHD. Urea is chosen as an easily measured surrogate for low-molecular-weight products of metabolism. Measuring total urea in the effluent fluid and continuous plasma urea concentration could allow calculation of clearance. However, this is cumbersome and approximations of dose are instead estimated from flow rates of dialysate.

The current recommendation for a minimum dose of RRT supports the delivery of at least 20 mL/kg per hour of CVVH, CVVHD, or CVVHDF. Usually this will require a

prescribed dose of 25 to 30 mL/kg per hour (if expecting treatment downtime or other interruptions in treatment, see “Prescribed Versus Delivered Dose”). Although higher doses of dialysis might be beneficial in selected patients, there is no evidence at this time of any benefit for a higher dose.

Other approaches for determining the dose of dialysis include using the clearance of molecules other than urea. Biochemical parameters such as the correction of electrolyte disturbances, the clearance of larger middle-weight molecules (such as β_2 -microglobulin), normalized protein catabolism ratio (nPCR), the anion gap, or the strong ion gap have been suggested as a “marker.” Clinical parameters of measuring dialysis include fluid balance, improvement and respiratory function, and nutritional markers. However, all of these markers remain investigational.

PRESCRIBED VERSUS DELIVERED DOSE

It is recommended that the prescription of dialysis should exceed that which is calculated to be adequate because there is a difference between what is prescribed and what is actually delivered. In a number of cases the delivered dose of dialysis is much smaller than what is prescribed.^{18,19} This can be due to interruptions in treatment due to hemodynamic instability, patient testing, circuit clotting, access recirculation, or other reasons why a patient may need to be disconnected from a machine.

TECHNICAL CONSIDERATIONS

CIRCUITS AND MATERIAL

ACCESS

Access for cRRT is accomplished through a central venous catheter. Vascular access is typically venovenous (VV), as opposed arteriovenous (AV). Intermittent techniques may be either AV (through AV fistulas or grafts) or VV (through venous catheters). The afferent limb of the blood circuitry is termed “arterial” regardless of whether this is truly arterial blood (AV) or not (VV). The returning, efferent limb is termed “venous.” AV fistulas or grafts in general may not be utilized as this would require needles to be continuously placed in the fistula or graft, which may damage it.

Several venous catheters are available; the double-lumen design is the most popular because of ease of insertion and good flow characteristics (Figs. 18.8 and 18.9).²⁰ Catheter failure, either from poor flow or clotting, is the most common cause of therapy underdelivery.²¹ System clotting and resistance to blood flow are some of the most frequent manifestations of catheter failure.

The most common sites for dialysis catheter placement are the femoral and internal jugular approaches. Femoral access requires the patient to remain in bed with no more than a 30-degree bend between trunk and leg.²² The internal jugular and subclavian approaches allow for mobilization, but carry with them the risk of pneumothorax or other intrathoracic trauma during placement. Femoral catheters shorter than 20 cm from hub to tip are associated with higher degrees of access recirculation. Catheters at

Figure 18.8 Double-lumen polyurethane central venous catheter for short-term use. From Ronco, C. In *Critical Care Nephrology*, 2/E. Phila., WB Saunders, 2008. (Fig. 222-006).

Figure 18.9 Double-lumen silicone (2D) central venous catheter for long-term use in action. From Ronco, C. In *Critical Care Nephrology*, 2/E. Phila., WB Saunders, 2008. (Fig. 222-007).

least 24 cm in length may produce improved flow rates, presumably because their tip reaches the inferior vena cava.²³ Use of the subclavian vein also includes the long-term risk of subclavian venous stenosis with repeated access and should be avoided. If a patient is to require an AV fistula in the future for end-stage renal disease, subclavian stenosis will delay maturation of the AV fistula placed on the same side.

TUBING

Long tubing for blood transport increases exposure of blood to nonbiologic surfaces, which cools the blood and increases the risk of clotting. The presence of sampling ports, entry ports, and stopcocks may create blood turbulence. Negative preblood pump pressures can easily introduce air into the circuit from a dysfunctional afferent limb of a catheter and would carry the risk of air embolism were it not for the presence of an air trap in the efferent limb of the circuit.

MEMBRANE

The details of membrane technology are beyond the scope of this chapter; however, the key highlights will be presented here.

The prevalent filter design in cRRT is hollow-fiber. The design consists of a blood compartment and a dialysate compartment, with respective inflow and outflow ports, separated by a semipermeable membrane. The hollow-fiber dialyzer consists of a tubular casing containing thousands of narrow capillary fibers through which blood flows between the arterial and venous header—two small spaces at either end of the filter where blood collects before and after running through the capillary fiber bundle. The capillaries, whose walls constitute the semipermeable membrane, are bathed in dialysate fluid, usually running in countercurrent fashion to blood flow.

The hollow-fiber design allows for the maintenance of systemic blood pressure. However, if clots form at the arterial header, a large surface area of membrane for electrolyte exchange may become unavailable.

Membranes may be made from (1) cellulose (e.g., cuprophane), (2) substituted cellulose (the free hydroxyl groups of cellulose, thought to activate complement, are bound to other substances, e.g., acetate in cellulose acetate membranes), (3) cellulosynthetic material (synthetic material incorporated with the cellulose polymer, e.g., Hemophan), and (4) synthetic material (made of noncellulosic materials, e.g., polysulfone, polyacrylonitrile [PAN], polyamide, and polymethyl methacrylate). A caveat for the use of the PAN filter is the concurrent use of angiotensin-converting enzyme inhibitors; the highly negatively charged membrane tends to bind and activate Hageman factor XII, with subsequent generation of bradykinin—a potential cause for anaphylactic reactions during long-term IHD with PAN. Administration of angiotensin-converting enzyme inhibitors may compound the problem because of their propensity to increase bradykinin production. The asymmetrical design of the polyamide membrane is well suited for UF and hemofiltration, but not for diffusion. PAN and cellulose acetate may have a better structure for diffusive therapies.

FLUIDS

Solutions of fluid take the form of either dialysate or replacement fluid. When hemofiltration is performed, replacement fluid composition dictates the resultant concentration of electrolytes. Similarly, knowing the composition of dialysate is important to determine to what equilibrium the electrolytes will settle. The sieving coefficients for relevant electrolytes and blood components are listed in [Figure 18.6](#). Elements with a negative charge that are small enough to cross the membrane do so at greater than unity. This apparent active transport is actually accomplished through a dynamic process similar to the Gibbs-Donnan effect seen in stagnant fluid balance. Because negatively charged proteins are unable to cross the membrane, chloride and bicarbonate move against a concentration gradient to maintain electrical neutrality. The exaggerated loss of these elements must be reflected in the replacement solution used.

Calcium and magnesium levels should be monitored closely, and replacement should be initiated at an early stage. Because therapy is effective in removing phosphate

and generally fluids do not contain phosphate, deficiencies develop, requiring supplementation. In general, these electrolytes are monitored every 12 hours.

As a general rule, to avoid undue hemoconcentration, the filtration rate for postdilutional hemofiltration should be no more than 15% of plasma flow through the filter. A 30% filtration fraction may be allowed in predilutional techniques.

Most fluids either contain lactate or bicarbonate at the base buffer. Other substances have also been considered, for example, the use of acetate or citrate. The use of citrate has an added advantage of being an anticoagulant. Acetate, although previously used extensively in long-term HD, may give rise to vasodilation, myocardial depression, and increased oxygen consumption.²⁴ As a result acetate should be avoided for cRRT.

Lactate undergoes hepatic conversion to bicarbonate on an equimolar basis. Although more stable than bicarbonate, there are numerous theoretical disadvantages to its use in cRRT. Although bicarbonate-based and lactate-based solutions can correct acidosis, bicarbonate is preferred because lactate-buffered fluids may require intravenous bicarbonate supplementation to achieve the same bicarbonate level.²⁵ The metabolism of exogenous lactate may be impaired in critical illness, with accumulation giving rise to a paradoxical metabolic acidosis.²⁶ Hyperlactatemia carries with it potential negative hemodynamic effects and metabolic complications, including increased protein catabolism and reduced adenosine triphosphate regeneration.²⁷ Complications of lactate overload are more likely to develop in patients with liver impairment and poor peripheral perfusion, particularly with high-volume treatment. Lactate intolerance is defined arbitrarily as a greater than 5 mmol/L increase in lactate levels during therapy.

Bicarbonate, although the more physiologic anion, also has specific drawbacks. It exists in solution with other ions in a state of equilibrium under specific physical conditions of temperature and pressure:

When CO₂ outgassing from the solution occurs (e.g., delivering bicarbonate using an open-top container), overall bicarbonate concentration may be reduced. Additionally, calcium and magnesium can precipitate out as insoluble carbonate compounds when sterilized with the buffer. Many bicarbonate-based solutions are produced with lower concentrations of both cations to help ameliorate this problem, with final mixing of the electrolyte and bicarbonate solutions just before use. A novel adaptation has electrolyte and bicarbonate solutions housed and sterilized in separate chambers of the same bag. A connecting valve is broken just before use to mix the two fluids. A final caveat to the use of bicarbonate is its apparent predilection to bacterial growth—at least in liquid bicarbonate concentrates used in long-term dialysis.

From the data available, although it seems that lactate-based substitution or dialysate fluids may be used safely in many patients, they should be avoided in patients with lactic acidosis or hyperlactatemia and in patients with hepatic failure. Bicarbonate-buffered solutions should be used in these cases.

ANTICOAGULATION

Circuit clotting is the most frequent cause of therapy interruption in cRRT. Various factors may account for the hypercoagulable state in a patient receiving cRRT.²⁸ Anticoagulation during cRRT is necessary to preserve the life of the extracorporeal circuit, to maximize the cRRT dose, and to minimize blood loss caused by clotting during cRRT. The ideal anticoagulant should have no effect on systemic hemostasis, no increase in hemorrhagic risk, only be limited to the extracorporeal circuit, optimize filter performance in circuit life, have a short half-life, be easily monitored, be easily reversible, and be inexpensive.²⁹ Options for anticoagulation of the circuit include using no anticoagulation, unfractionated heparin, low-molecular-weight heparin, citrate, and in rare circumstances thrombin antagonists or prostaglandins. **Box 18.4** lists current strategies to prevent circuit clotting. According to a world survey, 44% of those surveyed preferred unfractionated heparin for anticoagulation.³⁰

The option of no anticoagulation is usually used in patients with intrinsic coagulopathies such as hepatic failure or low platelet count. Circuits are usually primed with saline or heparin. Intermittent normal saline flushes may be used as well. The rates of filter clotting using this method vary widely. The mean filter life lies between 16 and 70 hours if the patient is coagulopathic. In cases of severe coagulopathy, shorter filter life may be seen. The disadvantages of no anticoagulation include the need for increased UF, the risk of dialyzer fiber rupture, and the extra nursing workload.³¹ The hemoconcentration induced by high UF volumes in CVVH and CVVHDF promotes clotting but may be minimized by predilutional fluid replacement. This comes at the price, however, of the inefficiency of ultrafiltering a mixture of just-infused replacement fluid and plasma, the proportions of which are important considerations in the cRRT prescription.

Unfractionated heparin works by inactivating factors Xa and IIa. The molecular weights of unfractionated heparins range from 5 to 30 kDa. The half-life of unfractionated

heparin is 90 minutes; however, this may be increased up to 3 hours in renal failure. The use of unfractionated heparin involves infusing continuous heparin at the arterial site of the circuit. Usually a bolus of 2000 to 5000 IU of heparin is used. Continuous infusion of heparin ranges between 5 and 20 units/kg per hour. In general, an activated partial thromboplastin time (aPTT) goal ranges between 34 and 45 seconds (1.5–2.0 times the normal). The reported circuit patency of this ranges between 20 and 40 hours. The advantages of using unfractionated heparin include the fact that it is effective, widely available, involves simple monitoring (i.e., aPTT), is easily reversed with protamine, is inexpensive, and has a short half-life. The disadvantages of the use of unfractionated heparin include systemic bleeding, unpredictable kinetics, aPTT not being a reliable predictor for bleeding, heparin resistance due to low antithrombin levels, and heparin-induced thrombocytopenia (HIT).

HIT may develop during heparin therapy.³² HIT begins with heparin exposure stimulating the formation of heparin-platelet factor 4 antibodies, usually 5 to 12 days after starting therapy. This triggers the release of procoagulant platelet particles. Both thrombosis and thrombocytopenia ensue and cause significant vascular complications. The prevalence of HIT varies among several subgroups, with greater incidence in surgical as compared with medical populations. HIT must be acknowledged for its intense predilection for thrombosis and suspected whenever thrombosis occurs after heparin exposure. In cRRT, this is manifested as recurrent filter clotting. The treatment of HIT mandates the cessation of all heparin exposure and the institution of an antithrombotic therapy, most commonly using a direct thrombin inhibitor. Current “diagnostic” tests, which primarily include functional and antigenic assays, have more of a confirmatory than diagnostic role in the management of HIT. Platelet aggregation studies are highly specific but lack sensitivity, so if they and heparin-induced platelet activation tests yield negative results, an enzyme-linked immunosorbent assay should be performed. Direct thrombin inhibitors are appropriate, evidence-based alternatives to heparin in patients with a history of HIT.

Direct thrombin inhibitors such as recombinant hirudin (lepirudin), danaparoid, and argatroban have been used in response to HIT.^{33,34} Bleeding resulting from overdosage of lepirudin or argatroban may be treated with the administration of fresh-frozen plasma. Hemofiltration with high-flux dialyzers also can reduce the plasma levels of hirudin.

Citrate regional anticoagulation works by chelating free calcium in the extracorporeal circuit and prevents the activation of calcium-dependent procoagulants. The anticoagulant effect of citrate is measured by ionized calcium levels. Anticoagulation is reversed by a calcium infusion. Normal blood levels of citrate are approximately 0.05 mmol/L. The bleeding time for a patient with citrate levels of 4 to 6 mmol/L can be infinite. Levels of 12 to 15 mmol/L are required for storing blood products for transfusion therapy. Citrate levels are usually performed in another facility or reference laboratory. Citrate has a plasma half-life of 5 minutes and is rapidly metabolized by the liver, kidney, and muscle cells. The extracorporeal clearance of citrate is the same as that of urea. The sieving coefficient ranges between 0.87 and 1.0. The clearance of citrate is the same for both CVVH and CVVHD.³⁵ The advantage of using citrate is that

it is regional and avoids bleeding complications. It also doubles as a buffer. It is more effective than heparin in studies,^{36,37} and it does not cause thrombocytopenia. Two early trials have shown that the use of citrate for regional anticoagulation yields no additional bleeding risk and leads to longer filter life.^{36,37} The largest citrate randomized controlled trial used citrate for anticoagulation in a postdilutional CVVH modality with blood flows of 220 mL per minute and citrate concentration of 3 mmol/L.³⁸ The study showed a lower mortality rate in patients receiving citrate regional anticoagulation. It is hypothesized that citrate inhibits leukocytes esterase, which may yield immunologic benefits. The major disadvantage of citrate stems from its metabolic complications and the complex protocols that are involved in its administration. Metabolic consequences of citrate use include metabolic alkalosis from citrate overdose or toxicity, metabolic acidosis in a setting of severe liver disease or hypoperfusion, hyponatremia from hyperosmolar citrate solutions (4% sodium citrate), and hypocalcemia and hypercalcemia from inappropriate calcium supplementation. The risk factors for citrate toxicity include liver disease, nursing or pharmacy errors leading to overdose, shock liver, and severe hypoperfusion states. The detection of citrate toxicity then becomes extremely important. One should expect citrate toxicity when noticing a rising anion gap, worsening metabolic acidosis, a falling systemic ionized calcium, escalating calcium infusion requirements, or a total calcium/systemic ionized calcium ratio greater than 2.5:1.³⁹ Strategies to manage citrate toxicity include decreasing the citrate infusion rate, decreasing the blood pump speed, and increasing the dialysate flow rate.

The decision as to which citrate protocol to use depends on the available citrate solutions, the method of citrate delivery, and the cRRT circuit options. Available commercial citrate solutions include concentrations of sodium citrate between 1.32% and 4%. Regional citrate anticoagulation may be performed using 4% trisodium citrate or with ACD-A solution (anticoagulant citrate dextrose solution, form A) containing 3% combined trisodium citrate (2.2 g/100 mL), citric acid (0.73 g/100 mL), and dextrose (2.45 g/100 mL) (Baxter-Fenwal Healthcare Corp., Deerfield, IL). ACD-A solution is preferred over trisodium citrate for routine regional citrate anticoagulation because it is less hypertonic and commercially prepared, potentially reducing mixing errors and the complications associated with overinfusion. Regional citrate anticoagulation protocols differ in the type of citrate preparation used, the mode of dialysis, and the ability to customize dialysis solutions. There is a fixed relationship between the blood flow in citrate delivery. The titration of citrate delivery should be based on the ionized calcium level. The amount of citrate delivered to achieve a blood citrate concentration of 4 mmol/L depends on the blood flow.⁴⁰

In a typical circuit (Fig. 18.10) arterial blood leading from the patient is first infused with citrate, which chelates the free ionized calcium. This blood then enters the filter where a calcium-free dialysate is used. Postfilter ionized calcium is monitored and used to titrate the citrate rate to ensure anticoagulation. The goal is to keep the ionized calcium at less than 0.35 mmol/L. The returning blood combines with the venous blood in the body, which normalizes the ionized calcium and prevents systemic anticoagulation. Calcium is

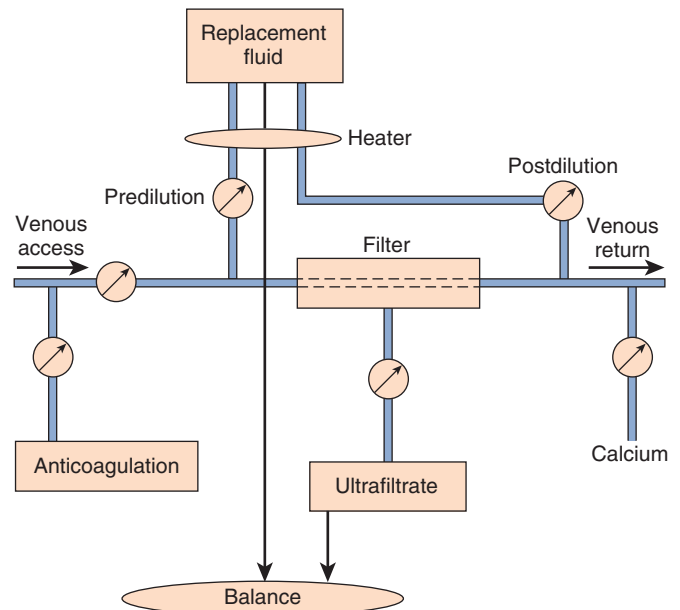

Figure 18.10 Schematic presentation of the continuous venovenous hemofiltration (CVVH) circuit. The circuit has a heater, a balance, and six pumps: a blood pump, an ultrafiltrate pump, two pumps for replacement (predilution and postdilution), an anticoagulation pump, and a calcium pump, to be used for citrate anticoagulation. From Ronco, C. In *Critical Care Nephrology*, 2/E. Phila., WB Saunders, 2008. (Fig. 248-001).

infused through a separate central line to replace the calcium lost in the ultrafiltrate. Citrate is metabolized primarily in the liver to bicarbonate and the bound calcium is released. For CVVH, citrate may or may not be a component of the replacement fluid.

A number of citrate protocols have been published. Protocols vary based on the number of fluid solutions utilized and commercial versus hospital specific fluid options. Published protocols include those from Massachusetts General Hospital,⁴¹ Gainesville,⁴² University of Alabama at Birmingham,⁴³ Sunnybrook,⁴⁴ and San Diego.⁴⁵

Low-molecular-weight heparins (such as enoxaparin, dalteparin, and nadroparin) have also been examined for their effect on circuit life.⁴⁶ Prostacyclin (prostaglandin I₂), a potent, short-acting, endogenous inhibitor of platelet aggregation, has also been studied.⁴⁷

Clinical experience with various agents and strategies influence choice. Table 18.6 reviews the advantages and disadvantages of each anticoagulation option.

THERAPEUTIC CONSIDERATIONS

PATIENT SELECTION

The question as to whether a patient needs renal replacement therapies is often difficult. There is no consensus as to the indication to start RRT, the criteria to start RRT, or the appropriate time for initiation of RRT. The conventional indications include volume overload, metabolic acidosis, hyperkalemia, uremia, azotemia without uremic manifestations, and drug overdose. The risks of dialysis include

Table 18.6 Anticoagulation Options

Feature	None	Heparin (Unfractionated)	Low-Molecular-Weight Heparin	Citrate
Advantages	Reduced risk of bleeding	Widely available Commonly used Short half-life Available reversal agent Monitoring accomplished with routine tests (aPTT) Low cost	Reduced risk of HIT Predictable kinetics (weight-based dosing) Monitoring not required	Strict regional anticoagulation—reduced risk of bleeding
Disadvantages	Risk of blood loss and clotting of system Microthrombi in filter may decrease efficiency	Narrow therapeutic index—risk of bleeding Heparin resistance HIT	Risk of accumulation in kidney failure If monitoring required, then a nonroutine test is necessary (anti-factor Xa) Incomplete reversal by protamine May be more expensive than unfractionated heparin	Overdose may be fatal Citrate may accumulate in patients with hepatic dysfunction and shock, which may result in metabolic acidosis and hypocalcemia Metabolic complications (acidosis, alkalosis, hyponatremia, hypocalcemia, hypercalcemia) Increased complexity requires a strict protocol

aPTT, activated partial thromboplastin time; HIT, heparin-induced thrombocytopenia.

hypotension, complications of placing vascular access, and air embolism (extremely rare). Additional risks and complications are listed in [Box 18.5](#). Patients in the ICU may have a number of conditions that impact the decision to initiate and prescribe RRT. In general, if patients have insufficient renal function, cRRT can be utilized to provide organ support much in the way that the ventilator is used to provide pulmonary support. Potential indications for renal support include nutrition, fluid removal in CHF, cancer chemotherapy, the treatment of respiratory acidosis in acute respiratory distress syndrome (ARDS), and fluid management in multiorgan failure.⁴⁸

TIMING OF INITIATION AND DISCONTINUATION

The use of the traditional biomarkers such as creatinine may delay the initiation of RRT. As a result, criteria such as RIFLE (risk, injury, failure, loss of kidney function, end-stage renal disease) have been used to grade the severity of one's AKI. It is known that the net fluid balance affects the outcomes of critically ill patients; fluid overload itself may be a marker of more severe disease. The difficulty in answering the question as to when to initiate RRT is that we will never know whether those who received dialysis would have recovered renal function if they had not received the therapy. There is no prospective randomized controlled trial to answer this question.

Dialysis is discontinued when the signs of renal recovery are apparent. This often takes the form of increased urine output, the decrease in biomarkers, or improvement in the patient's clinical status. cRRT may be switched to

intermittent forms when the patient is hemodynamically stable and daily fluid balance would afford intermittent treatments (usually no more than 2 L positive per day). However, as with the initiation of dialysis there is no consensus as to when the therapy should be discontinued.

RENAL RECOVERY

Recovery of renal function may manifest quite differently, depending on whether the patient was supported with intermittent or continuous techniques. Patients receiving cRRT may not show the typical signs of renal recovery because often their fluid balance is close to their premonitory weight. A decrease in the baseline serum creatinine without a change in the cRRT prescription may be the first sign of renal improvement. Urine creatinine and sodium may be more helpful in assessing patients receiving continuous rather than intermittent therapy. Recognizing these differences helps avoid extending therapy beyond what is needed and aids in hastening recovery when it has begun.

PHARMACOKINETICS DURING CONTINUOUS RENAL REPLACEMENT THERAPY

Altered drug kinetics is an important aspect of cRRT management, with some agents being cleared in significant quantities. Depending on membrane pore size, the passage of substances with molecular weights of 20,000 to 30,000 D is possible and may accommodate most drugs. As the clearance of drugs is limited to the free, non-protein-bound fraction, the degree of plasma protein binding dictates

Box 18.5 Possible Complications of Continuous Renal Replacement Therapy

Access

- Distal arterial insufficiency
- Embolism (air, thrombus, foreign body)
- Early
 - Early thrombosis
 - Infection
 - Hematoma (local/retroperitoneal)
- Late
 - Angiocutaneous fistula
 - Stenosis
 - Aneurysm (pseudo/real)
 - Loss of potential long-term intermittent hemodialysis arteriovenous fistula/graft site

Blood Pump

- Air embolism
- Blood loss

Lines

- Disconnection/hemorrhage
- Infection
- Thrombosis
- Kinking

Kidney

- Clotting
- Membrane rupture
- Backdiffusion of pyrogens from contaminated dialysate
- Membrane hypersensitivity reaction

Therapy

- Overanticoagulation/citrate intoxication
- Electrolyte abnormalities (see Table 18-7)
- Amino acid losses
- Fluid imbalance
- Hypothermia

whether dialysis or filtration would result in significant removal. Pharmacokinetics also is highly dependent on the drug's volume of distribution. Also, if the contribution of alternative elimination pathways to overall drug clearance is significant, then the clinical relevance of extracorporeal removal may be minimal.

A drug with low protein binding, a low volume of distribution, and low clearance by alternative pathways is one that would be cleared significantly by cRRT. Vancomycin and the aminoglycosides are good examples, and such agents require dosage adjustments if administered during continuous therapy.

Body clearance of drugs without significant tubular secretion or reabsorption is a linear function of creatinine clearance. Estimation of drug clearance by dialytic modalities is a more complex proposition and has to take account of dialysate and blood flow rates; the molecular weight of the drug; and membrane surface area, thickness, and composition. Nomograms used in the prediction of dialytic drug clearance may be used,⁴⁹ but these provide only a general

guideline. The impact of molecular weight differs between dialytic techniques and may be lower in CVVHD, which usually uses high flux membranes at a low dialysate flow rate (Q_D). Under these circumstances, the Q_D may approximate Q_F in the previous equations.⁵⁰ Drug clearance during CVVHDF may be estimated by combining calculations of filtrative removal with calculations of dialytic removal, but the complex interplay between convection and diffusion is not fully appreciated by this approach.

A final confounder of pharmacokinetic predictability is the impact of membrane adsorption of the drug, which may be substantial with PAN/AN69 materials and may vary depending on the frequency of filter changes. Such filters that remain in situ for long enough can start to release their adsorbed drug back into the circulation. In adjusting dosing of a drug that is significantly cleared by cRRT, a choice must be made either to shorten the dosing interval (to maintain plasma levels) or to increase the dose (to optimize peak concentrations) depending on that agent's mode of action. Formulas have been developed to estimate adjustments of dose and dosing interval.^{50,51}

Published data do exist to help guide drug dosing during cRRT, but they come from a variety of sources and are often not standardized. The use of aids to estimate dose, such as those detailed previously, is required.

COMPLICATIONS OF THERAPY

Perhaps the most frequent problems encountered are electrolyte derangements (Table 18.7). With the use of hemofiltration, as we have seen earlier, the replacement solution determines the final electrolyte outcome. The replacement solution must reflect the sodium, chloride, and bicarbonate concentrations that one would like to achieve in patient serum and the relative loss via the hemofilter. The substance's particular sieving coefficient can be used to determine therapeutic losses, following the formula:

$$[]_s \times S_{\text{coef}} \times Q_F$$

where $[]_s$ is the incoming blood concentration of the substance, S_{coef} is its sieving coefficient, and Q_F is the UF rate (see Fig. 18.6). Not only the actual replacement fluid, but *all* fluid must be taken into consideration. Frequently, drug vehicles with water or hypotonic hyperalimentation solutions are calculated in the fluid exchange, but not in the electrolyte balance. The resultant loss of sodium (in the hemofiltrate) and the replacement with hypotonic solution produce a true hyponatremia. The exaggerated loss of bicarbonate and chloride also produces variations if these balances are not considered in the total composition delivered to the patient.

Ionized calcium, magnesium, and phosphate also are lost during continuous hemofiltration and HD. This is a different situation from that of intermittent therapies, where these substances are usually retained and need to be subject to a limited intake. It is not unusual for patients to require the addition of magnesium, calcium, and phosphate to cover therapeutic losses and establish normal plasma levels. Serum levels should be checked frequently (up to every 12 hours), and replacement should be calculated as noted earlier.

Table 18.7 Common Electrolyte Problems During Continuous Renal Replacement Therapy with Their Solutions

Problem	Solutions
↓ Na ⁺	<ol style="list-style-type: none"> 1. Change all fluid infusions to 0.9% saline or equivalent. 2. Increase dialysate sodium (add NaCl). 3. Ensure adequate sodium delivery in replacement solution.
↓ HCO ₃ ⁻	<ol style="list-style-type: none"> 1. Ensure adequate HCO₃⁻ concentration in dialysate/replacement. 2. With lactate-based solutions, consider change to HCO₃⁻ base (especially in liver failure or shock). 3. Increase HCO₃⁻ in TPN.
↓ Ca ²⁺	<ol style="list-style-type: none"> 1. Increase Ca²⁺ in TPN. 2. Add Ca²⁺ to dialysate/replacement (if HCO₃⁻ base, may need to add elsewhere). 3. Ensure adequate oral Ca²⁺ intake if appropriate.
↓ PO ₄ ²⁻	<ol style="list-style-type: none"> 1. Pay close attention to antacid use (acts as gastrointestinal PO₄²⁻ binder; may need to be stopped). 2. Increase PO₄²⁻ in TPN.
↓ Mg ²⁺	<ol style="list-style-type: none"> 1. Increase Mg²⁺ in TPN. 2. Add Mg²⁺ to dialysate/replacement (if HCO₃⁻ base, may need to add elsewhere). 3. Supplement as MgCl or MgSO₄.
↑/↓ K ⁺	<ol style="list-style-type: none"> 1. Avoid repeated bolus therapy if ↓ K⁺. 2. Adjust K⁺ in dialysate/replacement. 3. If ↑ K⁺ uncontrolled, add intermittent therapy. 4. May need addition or discontinuation of K⁺ binder therapy.

TPN, total parenteral nutrition.

Continuous HD procedures also require frequent electrolyte monitoring. Serum values generally reflect the dialysate concentration of that particular solute. Establishing a potassium floor of 4 mEq/L merely requires that the dialysate concentration of potassium also be set at 4 mEq/L. Common electrolyte problems seen in patients receiving continuous therapies are listed in Table 18.7. Box 18.5 lists other possible complications.

ETHICAL CONSIDERATIONS

Bioethical issues related to cRRT have been widely discussed. Many times the use of dialysis involves the decision of tapering aggressive interventions. Oftentimes, the kidney appears to be the last organ in the chain of multiorgan failure. From the family's perspective the use of dialysis is usually not a predefined life-sustaining measure. The use of dialysis is often a source of conflict of attitudes between the treating teams of the patient. The decision to initiate dialysis should be a discussion between the treating team, the one prescribing cRRT, and the patient and caregivers. This can either be a long-term treatment for a short-term test case in the setting of longstanding chronic disease or set an advance

illness. The discontinuation or withdrawal many times is the decision of the entire team.

NONRENAL APPLICATION OF CONTINUOUS THERAPIES

The hemodynamic stability of continuous renal therapies has contributed to their use in situations in which fluid loss is desired but patient status has restricted more standard dialytic or other therapeutic interventions. The ability to manipulate a continuous extracorporeal blood circuit also has opened wide opportunities to assess a variety of different nonrenal applications (Fig. 18.11). The basic circuit has been incorporated into liver assist devices (currently undergoing clinical testing), and the ability to either warm or cool circulating blood has applications in clinical and experimental medicine. The adsorptive nature of different membrane types and structures also has been the focus for potential therapeutic interventions.

Perhaps the most frequently cited area of use has been isolated UF for the treatment of CHF. Several studies have described the utility of UF for the removal of extravascular lung water in models subjected to pulmonary damage or fluid overload.

The sieving and adsorptive qualities of the continuous extracorporeal circuit have found their way into the manipulation and eventual management of patients with sepsis or systemic inflammatory response syndrome. Numerous experimental studies have touted the ability of various membranes either to remove or to adsorb various cytokines. Tumor necrosis factor- α , interleukin 1, interleukin 6, and interleukin 8 have been the most studied, but endothelin, lipopolysaccharide fragments, and C3a and C5a also have been identified. High-volume zero-balance hemofiltration has been the focus of several animal experiments, in which control of systemic inflammatory response syndrome has been noted.

Clinical translation of this approach consistently has failed to confirm bench findings for many reasons. Extracorporeal removal of inflammatory mediators may be negligible in relation to endogenous turnover. Extracorporeal treatment was usually initiated within a short time frame after induction of experimental sepsis; this is almost impossible to achieve in the real world. Potentially beneficial substances, such as interleukin 10, water-soluble vitamins, and elements such as zinc or selenium, also may be cleared. As a result, clinical application of these techniques has been viewed with some caution.

The adsorptive qualities of specific membranes (AN-69, PAN) have been the most accepted mode of clinical attempts at cytokine control. Although early data seem to point to an impact in lowering blood cytokine levels, a cumbersome and costly exchange of circuit filters, with saturation seen at 2 to 4 hours, brings into question the practicality of this approach.

SUMMARY

The use of continuous extracorporeal therapies in the management of AKI has added another therapeutic option to the armamentarium of clinicians caring for an increasingly

Figure 18.11 Modalities of cRRT. Techniques available today for renal replacement in the intensive care unit. complicated ICU population. The heterogeneity of the ICU AKI experience warrants the availability and use of the appropriate form of renal support as dictated by the individual patient's condition, allowing the patient to derive the greatest potential benefit. Applying these various tools in a rational and cost-effective manner is the true challenge for physicians who practice intensive care medicine.

KEY POINTS

- cRRT holds many theoretical advantages over intermittent modalities, including maintenance of hemodynamic stability, enhanced fluid removal, and increased dialysis dose delivery. Despite these benefits, there has yet to be a clear outcome advantage with this form of therapy.
- The role of therapy application (diffusion versus convection) may be decided less on the character of the therapy and more on the potential for membrane

KEY POINTS (Continued)

- clearance: larger molecules (convection) and smaller molecules (diffusion).
- A typical cRRT prescription would include the following elements: blood flow 250 to 300 mL per minute; dialysate or replacement flow rate 20 to 25 mL/kg per hour; and UF rate as determined by the daily fluid balance goal of the patient. Owing to treatment interruptions, the patient may not receive the prescribed dose.
- Central venous access is necessary for cRRT and is best accomplished by a dialysis catheter placed preferably in the internal jugular or femoral vein.
- A variety of bicarbonate-based and lactate-based solutions are available commercially. Close evaluation of the various components helps identify the appropriate composition for the particular patient need. In general, potassium concentrations of 4 mEq/L

Continued on following page

KEY POINTS (Continued)

- are used to maintain or raise a patient's serum potassium. Concentrations of 0 or 2 mEq/L are used to lower a patient's serum potassium.
- Many different strategies currently are available to help prevent clotting of the extracorporeal circuit: heparin, citrate, and argatroban are the most commonly used.
 - There is no clear consensus as to when to start or stop cRRT. Criteria for discontinuation of cRRT include hemodynamic stability, recovery of renal function, and a net daily fluid balance of no more than 2 L (to ensure that a patient may receive HD without large UF requirements).
 - cRRT affects the pharmacokinetics of many drugs prescribed in critical care practice. Knowledge of the extracorporeal prescription and individual properties of the drug helps determine appropriate dosing during ongoing continuous treatment.
 - Ethical issues must be considered prior to offering, initiating, and discontinuing cRRT.

SUMMARY AND CONCLUSIONS

Critically ill patients often experience unpleasant sensations including pain, anxiety, dyspnea, and other forms of distress.¹⁻⁴ This is particularly true for mechanically ventilated patients who make up a significant proportion of intensive care unit (ICU) patients. The ICU environment, and ICU care in general, is widely regarded as not ideally suited to patient comfort. For example, most patients may have surgical incisions and often have a variety of indwelling tubes and vascular catheters. Further, sleep disruption is common, sound and light levels are often excessive, and patient communication and mobility are impaired. Core principles of ICU care are to provide comfort to our patients and to relieve their suffering.⁵⁻⁸ Although nonpharmacologic interventions can improve patient comfort,⁹ clinicians have relied upon administration of analgesic and sedative medications to reduce the sensation of pain and anxiety, to control agitation, and to enhance tolerance of the ICU environment.¹⁰⁻¹² However, clinical experience and research over the past decade have demonstrated the hazards associated with excessive or unnecessarily prolonged sedation and the importance of accurately achieving targeted analgesia and sedation.¹³⁻¹⁷ Newly revised clinical practice guidelines from the Society of Critical Care Medicine (SCCM)⁶ and other recent guidelines and reviews on sedation and analgesia¹⁸⁻²³ highlight the importance of adopting a management approach that is patient-focused and strives to use the lowest effective dose of medications. The past decade has also brought a greater appreciation for the importance that development of delirium in the ICU has for long-term outcomes including downstream cognitive dysfunction.^{6,24-29} The topic of ICU delirium is reviewed in detail elsewhere in

this textbook (Chapter 72). Finally, the use of neuromuscular blocking agents (NMBAs) to achieve therapeutic paralysis is undergoing reevaluation, particularly for optimizing management of acute respiratory distress syndrome (ARDS).³⁰⁻³³ The use of sedatives, analgesics, and NMBA in managing critically ill patients is reviewed in this chapter.

Surveys and clinical reports indicate that the majority of ICU patients experience pain, dyspnea, or other forms of distress and receive sedative and analgesic medications.^{10-12,34} Some of the key terms and definitions related to patient distress and neurobehavioral abnormalities in ICU patients are presented in [Box 19.1](#).³⁵ Much of the discomfort is related to various stressors. In one case series, being in pain, being unable to sleep, and having tubes in the nose or mouth were the most prominent stressors reported by recovering ICU patients.⁴ Clearly, providing relief from these and other issues is an important goal of analgesic and sedative therapy. Consequences of suboptimal analgesia and sedative therapy can include problems related to inadequately controlled pain and anxiety or excessive sedation. Agitation, defined as “excessive motor activity associated with internal tension,” is perhaps the most widely recognized manifestation of uncontrolled anxiety or pain and is a problem because it can result in dramatic events, such as self-removal of important tubes and catheters, or even violence directed toward care providers. Overt agitation is a common occurrence among critically ill patients with rates as high as 20% of patient-shifts and nearly three quarters of patients during ICU stay.³⁵⁻³⁸ Self-removal of critical indwelling tubes and vascular catheters is the most common manifestation of overt agitation, placing the patient in peril from loss of an

Box 19.1 Terms for Patient Distress and Neurobehavioral Abnormalities in the Critically Ill

Agitation: Excessive motor activity associated with internal tension. The motor activity usually is nonpurposeful but may be irrationally purposeful and counterproductive.

Anxiety: A sustained state of apprehension with accompanying autonomic arousal in response to a real or perceived threat.

Apprehension: The subjective experience of dread and foreboding.

Autonomic arousal: Stimulation of the sympathetic and parasympathetic nervous systems and the autonomically controlled humoral axes. Autonomic arousal is manifested physically by tachycardia, systolic hypertension, hyperventilation, and diaphoresis.

Cognitive dysfunction: Reduced memory and analytical skills, confusion, and impaired judgment.

Coma: A state of unarousable unresponsiveness.

Defensive withdrawal: A physical and psychological reaction to an unpleasant situation manifested by avoidance, reduced responsiveness, and hypervigilance.

Delirium: An acute, potentially reversible impairment of consciousness and cognitive function that fluctuates in severity. Manifestations include apprehension, agitation, cognitive distortion, abnormal thought processes (including hallucinations), and impairments of short-term memory, arousal, and attention.

Distress: A global term for suffering, strain, or misery affecting the body or the mind.

Dyspnea: The experience of difficulty or distress in breathing.

Obtundation: Pathologic drowsiness, often accompanied during wakefulness by reduced attention and interest in the environment.

Pain: An unpleasant sensory or emotional experience associated with either actual or potential tissue damage that typically leads to evasive action.

Patient-ventilator asynchrony: An erratic breathing pattern in mechanically ventilated patients characterized by suboptimal matching of patient respiratory drive and mechanics with ventilator function.

Stress response: Reactions of the body and the mind to threats or forces of a deleterious nature that tend to upset physiologic homeostasis.

Stupor: A sustained state of spontaneous unarousability interruptible only by vigorous, direct external stimulation.

Modified with permission from Sessler CN, Grap MJ, Brophy GM: Multidisciplinary management of sedation and analgesia in critical care. *Semin Respir Crit Care Med* 2001;22:211-225.

artificial airway and positive-pressure ventilation, abrupt cessation of infusion of critical medications such as vasopressors, and the risk and discomfort associated with reinsertion of tubes and lines.³⁹ In prospective studies, device removal rates range widely from 22 to 157 events per 1000 patient-days^{40,41} and have an associated added cost.⁴² Documentation of patient agitation has become commonplace with the broad use of scales that address both sedation and agitation.⁴³ In addition to device removal and care provider assault, agitation is often accompanied by an intense stress response with catecholamine surge resulting in tachycardia,

hypertension, and tachypnea.^{44,45} Withdrawal of continuous infusion sedative and analgesic medications to promote awakening is associated with a two- to fourfold increase in circulating catecholamines⁴⁶ and can produce evidence of withdrawal that peaks within 6 hours.⁴⁷ Adrenergic stress response has been linked to hypercoagulability, glucose intolerance, increased catabolism, immunosuppression, sleep disturbance, and delirium. Further this can precipitate adverse events such as myocardial ischemia, increased intracranial pressure (ICP), tachyarrhythmias, and complications of uncontrolled hypertension in susceptible individuals.⁴⁸ Finally, it is also worth considering that overt agitation can be a marker for extreme distress that has a cause that may be life-threatening or that could be rapidly resolved upon recognition and management.^{21,35,36} Endotracheal tube malposition or obstruction, severe chest pain from myocardial ischemia, and tension pneumothorax are examples of conditions for which severe agitation in the nonverbal patient may be an important clue to an urgent dangerous situation. In fact, agitation was a common clinical antecedent prior to cardiopulmonary arrest in one study.⁴⁹

Although the primary effect of analgesic and sedative medications is the relief of pain, anxiety, agitation, and related problems, such relief is usually accompanied by reduced level of consciousness. Excessive and unnecessarily prolonged impaired sensorium is associated with additional complications—as a result of excessively deep sedation (i.e., pressure sores or nerve compression from reduced movement), or as a result of sedation-related delayed recovery from critical illness and mechanical ventilation with higher rates of complications and interventions related to longer ICU length of stay (LOS). Further, long-term neuropsychological consequences of ICU sedation are increasingly recognized.²⁵ Accordingly, it is critical to take a structured approach to managing analgesia and sedation, which includes carefully examining the specific patient-focused goals of therapy, using validated tools for evaluation and monitoring, and implementing management that explicitly targets using the lowest effective dose of the best analgesic and sedative medications for the specific patient. Some important components for analgesia and sedation management gleaned from prior reviews and current clinical practice guidelines are listed in [Box 19.2](#).^{6,19-23}

Analgesia and sedation are most effective when they are patient-focused because each patient and circumstances have unique features that may influence the response to therapy. Some of the predisposing and precipitating conditions that can contribute to the development of anxiety, pain, and delirium are noted in [Figure 19.1](#).^{19,35} For example, a variety of underlying medical conditions—such as alcohol or substance abuse,⁵⁰ psychiatric disorders, and chronic pain—can influence the likelihood of developing anxiety, pain, or delirium and can affect the response to therapy.³⁷ Further, inadvertent discontinuation of home medications such as opioids, benzodiazepines, or antipsychotic medications because of lack of awareness of their prior use is not uncommon with unscheduled ICU admissions and is an important reason to perform detailed medication reconciliation with patients and their family members. Although the notion that “ICU psychosis” is actually caused by the ICU is misleading, it is clear that excessive noise, light, and repeated

Box 19.2 Key Concepts for Management of Sedation and Analgesia

1. Develop a multiprofessional, structured approach for managing analgesia and sedation in your ICU. Utilize key user buy-in, education, protocols, order sets, ICU rounding checklists, and other tools to promote durable integration into patient care.
 2. Perform patient assessment and optimize ICU environment:
 - a. Identify predisposing and precipitating factors; manage correctable factors.
 - b. Optimize patient comfort and tolerance of the ICU environment, including controlling light and noise and promoting sleep.
 - c. Optimize mechanical ventilation settings for patient-ventilator synchrony.
 - d. Provide preemptive analgesia to alleviate pain associated with painful procedures.
 3. Regularly perform and document structured patient evaluation and monitoring:
 - a. Establish and communicate treatment goals.
 - b. Assess presence and severity of pain as well as response to therapy using self-report or a validated pain assessment tool.
 - c. Assess level of sedation using a validated sedation scale as well as response to therapy.
 - d. Assess presence and severity of agitation using a validated agitation scale.
 - e. Identify delirium using a validated delirium assessment instrument.
 4. Implement a structured, patient-focused management strategy:
 - a. Select analgesic and sedative drugs based on patient needs and unique characteristics (such as alcohol
- or substance abuse), drug allergies, organ dysfunction (particularly renal or hepatic dysfunction), need for rapid onset or offset of action, anticipated duration of therapy, prior response to therapy, and published evidence.
- b. Focus first on analgesia, then sedation. Use opioids as primary analgesics, but consider adding adjunctive agents or interventions.
 - c. Evaluate and manage severe agitation, including a search for causative factors, and perform rapid tranquilization.
 - d. Identify delirium, correct precipitating factors, and administer appropriate medications to reduce the intensity and duration of delirium.
 - e. Titrate analgesic and sedative drugs to a defined target, using the lowest effective dose and aiming for light level of sedation.
 - f. Implement a structured strategy to avoid accumulation of medications/metabolites: utilize scheduled interruption of medications, or intermittent dosing, of analgesic and sedative drugs. Perform safety screen to select proper candidates for interruption of sedation.
 - g. Link reductions in analgesic and sedative drugs to spontaneous breathing trials and to early mobilization.
 - h. Avoid potential adverse effects of analgesic and sedative drugs; quickly identify and manage adverse effects that occur.
5. Recognize and take steps to ameliorate analgesic and sedative drug withdrawal during de-escalation of therapy.

Box 19.3 Conditions and Medications Associated with Agitation and Delirium

Conditions

Central nervous system (CNS) disorders—stroke
 Infections—sepsis, encephalitis
 Withdrawal from sedative agent (alcohol, benzodiazepine, opioid, nicotine)
 Medication intoxication (CNS stimulants)
 Metabolic disorders (hypoglycemia, thyrotoxicosis)
 Electrolyte disorders (hyponatremia, hypermagnesemia)
 Poisoning
 Hypoxia
 Endotracheal tube or tracheostomy tube malposition or occlusion
 Patient-ventilator asynchrony
 Pneumothorax
 Pain (cardiac/vascular/gut ischemia, headache, distended viscus—e.g., bladder, bowel, indwelling tubes/catheters/devices, poor body or limb position)
 Sleep deprivation

Medications

Antibiotics
 Anticholinergics
 Anticonvulsants
 Antihistamines
 Benzodiazepines
 Cardiovascular medications
 Corticosteroids
 Opioids
 Nonsteroidal anti-inflammatory agents

patient awakening to check vital signs or perform tests at night contribute to fragmented sleep and can provoke anxiety and delirium.⁵¹⁻⁵³ Acute medical illness, surgical interventions, mechanical ventilation and the interface (i.e., tracheostomy tube, endotracheal tube, oronasal mask), and nursing interventions such as suctioning and turning can contribute to pain and discomfort.^{3,4,54} A variety of conditions and medications have been associated with the development of delirium and agitation, as displayed in **Box 19.3**.³⁵

PAIN MANAGEMENT IN THE INTENSIVE CARE UNIT

Pain is widely experienced in the ICU setting and can result from invasive procedures, surgery, and monitoring devices, as well as more direct stimuli from injury, inflammation, and immobility.⁵⁵ Treating pain is a core component of the caregivers' responsibility to relieve suffering and offers the physiologic benefits of relieving pain-induced altered glucose control, myocardial ischemia, immune system dysfunction, hypercoagulability, ventilator asynchrony, impaired ventilation, and disrupted sleep.⁵⁵ Mechanisms for these downstream effects include neurohormonal derangements, catecholamine release, and stress response.^{55,56}

Effective treatment of pain begins with the assumption that pain is widely present and that caregivers should

systematically evaluate each patient for the presence of pain and its intensity and characteristics, on a repetitive basis.^{6,8,9,55} Caregivers tend to underrecognize pain and often fail to preemptively treat pain.^{3,57} Accordingly, clinicians should err on the side of presuming pain is present—particularly when considering that it is far more effective to prevent and manage pain at an early stage than after it has become severe. Ideally, pain should be described in regard to location, duration, type, exacerbating and relieving factors, and intensity. Pain is sometimes conceptualized by subtypes, including somatic, visceral, and neuropathic, because manifestations and management can be different.⁵⁵ For example, somatic pain is typically dull and aching, often localized, and responds well to opioids and nonsteroidal anti-inflammatory agents (NSAIDs). In contrast, visceral pain is often cramping and colicky and may respond to anticholinergic therapy, although the burning and shooting neuropathic pain is often best treated with antidepressant and anticonvulsant agents.

Because pain is a subjective interpretation by an individual, the ability of that individual to convey the presence and magnitude of pain is of great value in guiding evaluation and management.⁵⁸ Detailed verbal communication by ICU patients is often limited; however, use of simple tools such as the numerical rating scale or a series of cartoon faces ranging from smiling to crying can facilitate communication by pointing or nodding in the nonverbal but cognitively intact patient.⁵⁹ A simple horizontal 0 to 10 numerical scale with enlarged font was judged to be most feasible and valid in one study of pain intensity rating scales.⁶⁰ Other techniques to enhance the use of self-reporting of pain include adding descriptive words to the numerical scale, carefully explaining the tool and correct use with each encounter, providing glasses and hearing aids if necessary, allowing adequate time for instructions and patient response.⁵⁸ Use of a scale that incorporates descriptive pictures, like the faces scale, can facilitate self-reporting of pain intensity regardless of potential language barriers.

Many ICU patients are cognitively impaired and self-reported pain intensity is not feasible. Accordingly, clinicians must rely upon observed behaviors that have been documented to correlate well with self-reported pain or to be associated with noxious stimuli.^{54,57,61-63} Investigators have combined behaviors into structured assessment tools. Interestingly, much of the early work in pain assessment for noncommunicative ICU patients was in infants and young children, resulting in the development of the COMFORT scale,⁶⁴ the Face, Legs, Activity, Cry and Consolability (FLACC) observation tool,⁶⁵ and others. Subsequently a variety of pain assessment tools for nonverbal critically ill adults have been developed, validated, and thoroughly reviewed.^{58,66,67} In the 2012 SCCM guidelines,⁶ published pain observation tools for adults in the ICU were identified as the Critical-Care Pain Observation Tool (CPOT),⁶⁸ the Behavioral Pain Scale (BPS),⁶⁹ the Behavioral Pain Scale—Nonintubated (BPS-NI),⁷⁰ the Non-Verbal Pain Scale (NVPS),⁷¹ the Pain Behavioral Assessment Tool (PBAT),^{54,72} and the Pain Assessment, Intervention, and Notation (PAIN) tool.⁷³ Extensive psychometric testing was performed including examination of scale development, testing of reliability, and testing of validity, feasibility, and scale relevance or impact of implementation in ICU patient outcomes yielding

Table 19.1 Critical Care Pain Observation Tool (CPOT)

Indicator	Description	Observations	Score
Facial expression	No muscular tension observed	Relaxed, neutral	0
	Presence of frowning, brow lowering, orbit tightening, and levator contraction	Tense	1
	All of the above facial movements plus eyelids tightly closed	Grimacing	2
Body movements	Does not move at all (does not necessarily mean absence of pain)	Absence of movements	0
	Slow, cautious movements, touching or rubbing the pain site, seeking attention through movements	Protection	1
	Pulling tube, attempting to sit up, moving limbs/ thrashing, not following commands, striking at staff, trying to climb out of bed	Restlessness	2
Muscle tension	No resistance to passive movements	Relaxed	0
	Resistance to passive movements	Tense, rigid	1
	Strong resistance to passive movements; inability to complete them	Very tense or rigid	2
Compliance with the ventilator	Alarms not activated; easy ventilation	Tolerating ventilator or movement	0
	Alarms stop spontaneously	Coughing but tolerating	1
	Asynchrony: blocking ventilation; alarms frequently activated	Fighting ventilator	2
OR			
Vocalization (extubated patients)	Talking in normal tone or no sound	Talking in normal tone or no sound	0
	Sighing, moaning	Sighing, moaning	1
	Crying out, sobbing	Crying out, sobbing	2
Total, range			0-8

a maximum score of 25 and weighted score of 0 to 20. The CPOT had the highest weighted score of 14.7, followed by the BPS with 12.0,⁶ and these two scales are recommended in the 2012 SCCM guidelines as the most valid and reliable behavioral pain scales for monitoring pain in adult medical, postoperative, and trauma ICU patients who are unable to self-report and in whom motor function is intact and behaviors are observable.⁶ CPOT and BPS are displayed in [Tables 19.1](#) and [19.2](#). Pain is often accompanied by changes in vital signs, with tachycardia, hypertension, and tachypnea being most common. However, changes in vital signs are inconsistently associated with pain, with many confounding factors that can mask anticipated changes—such as administration of beta blockers, as well as lack of specificity with many other causes of tachycardia, hypertension, and tachypnea.⁷⁴ Accordingly, 2012 SCCM guidelines recommend against the use of vital signs (or observational pain scales that include vital signs) alone for pain assessment in adult ICU patients.⁶ However, it is acknowledged that vital signs may be an important cue to prompt further pain assessment.⁶ Other potentially useful approaches include evaluating pain risk profile, use of surrogate (such as family members) report,⁷⁵ and performance of an analgesic trial.^{3,55,58}

There are several important tenets for managing pain in the ICU. First, when initiating sedative treatment for mechanically ventilated ICU patients, analgesia should be the first step, followed by the addition of a sedative-anxiolytic agent. This “analgesia first” approach is suggested in the 2012 SCCM guidelines⁶ as well as many expert reviews.^{18-23,55} Second, the use of preemptive analgesia should be

Table 19.2 Behavioral Pain Scale (BPS)

Item	Description	Score
Facial expression	Relaxed	1
	Partially tightened (e.g., brow lowering)	2
	Fully tightened (e.g., eyelid closing)	3
	Grimacing	4
Upper limbs	No movement	1
	Partially bent	2
	Fully bent with finger flexion	3
Compliance with ventilation	Permanently retracted	4
	Tolerating movement	1
	Coughing but tolerating ventilation for most of the time	2
	Fighting ventilator	3
	Unable to control ventilation	4

administered prior to the performance of interventions, such as chest tube removal, that are associated with having a high likelihood of producing pain.⁶ It is more effective to prevent pain or manage it at an earlier and milder stage than after pain has become severe.

Successful pain management in the ICU incorporates pharmacologic and nonpharmacologic treatment.⁹ Parenteral opioids are the primary agents used to treat pain in the ICU setting, but use of selected nonopioid and atypical agents can enhance pain relief and may reduce adverse effects. The major parenteral opioids for continuous infusion in ICU patients—fentanyl, morphine, hydromorphone, and remifentanyl (see Table 19.4)⁹—are generally considered to be equivalent in regard to analgesic potential as well as class-based adverse effects such as respiratory depression or reduced level of consciousness. Important differences among agents in regard to lipid solubility, volume of distribution (Vd), half-life, clearance, metabolism, and active metabolites have important effects on onset, peak, and offset of action, potency, and the influence of renal or hepatic dysfunction.⁹ Some of the medication features that can influence opioid selection for a particular patient are noted in Table 19.3. For example, morphine sulfate is metabolized to several active metabolites, including morphine-6-glucuronide, which is as active as the parent compound and accumulates in renal failure, resulting in prolonged effects including analgesia but also somnolence and respiratory depression.⁷⁶ The rapid equilibration of fentanyl from plasma to lipid-rich brain tissue is responsible for its rapid onset of action but its high lipophilicity also contributed to large Vd and delayed offset of action after prolonged infusion. Remifentanyl has a small Vd, and rapid clearance with metabolism by esterases, yielding a short half-life and rapid offset of action that is independent of renal and hepatic function.^{77,78} Several opioids not listed deserve mention. Meperidine has the potential for neuroexcitatory adverse effects such as seizures⁷⁹ and is not recommended for ICU use.⁶ Methadone can slow the development of tolerance to other opioid agents when coadministered but has unpredictable pharmacokinetics and is not administered by continuous infusion.⁶ Methadone is also a potent precipitating agent for prolonging the rate-corrected QT interval (QTc).^{80,81} Although opioids are most effective for pain management in the ICU patient, these agents have a well-documented propensity to produce adverse effects (AEs), which are reviewed, along with comments for each AE, in Table 19.4.^{9,55} Comprehensive pain management should include awareness of the likely adverse effects and how best to avoid them and to recognize and manage them.

It is often advantageous to use the lowest effective dose of an opioid analgesic, particularly when intolerable side effects are present. Additionally, there are clinical settings in which a nontraditional approach may be more effective, safer, and better tolerated. Employment of alternative or complementary approaches such as adding nonopioid or atypical analgesic agents, use of epidural or other neuraxial alternatives to parenteral opioid, and use of complementary nonpharmacologic interventions should be considered in selected cases.⁹

NONOPIOID AND ATYPICAL AGENTS

The use of nonopioid medications is best approached from the perspective of differentiating neuropathic pain for which anticonvulsants, antidepressants, and other agents play a primary role versus non-neuropathic pain for which opioids are the first line of therapy and other agents are

used to reduce opioid dosage and reduce side effects. There is compelling evidence that the addition of oral gabapentin or carbamazepine to opioids provides superior pain relief for neuropathic pain in ICU patients when compared to opioids alone,^{82,83} and this use is strongly recommended in this setting in the 2012 SCCM guidelines.⁶ Pharmacotherapy for neuropathic pain has been extensively studied in randomized controlled trials (RCTs) in non-ICU patients, and medications including tricyclic antidepressants, selective serotonin receptor inhibitors (SSRIs), serotonin and norepinephrine reuptake inhibitors (SNRIs), anticonvulsants, tramadol, dextromethorphan, ketamine, topical capsaicin, lidocaine patch or gel, cannabinoids, and other agents have shown efficacy, albeit often in trials with small sample size and with associated side effects.⁸⁴

Nonopioid adjuvant therapy in non-neuropathic pain can help reduce the quantity of opioids administered and potentially decrease the incidence and severity of opioid-related side effects. Such agents have been extensively studied in various non-critically ill populations—primarily postoperative patients, with efficacy demonstrated in meta-analyses of RCTs for corticosteroids, NSAIDs, acetaminophen, ketamine, and others.⁸⁵⁻⁸⁸ There is relatively limited research in ICU patients and most of the RCTs performed with ICU patients have been in the postoperative setting. Best studied in the ICU population are IV (intravenous) acetaminophen, cyclooxygenase inhibitors, and ketamine.⁸⁹⁻⁹¹ As a result of the limited evidence base in ICU patients, the 2012 SCCM guidelines generally support this approach as a weak recommendation for the addition of nonopioids for non-neuropathic pain.⁶ The potential benefits as well as risks of nonopioids for ICU use are further discussed in reviews published in 2009.^{9,55}

REGIONAL ANESTHESIA AND ANALGESIA

Although systemic administration of opioids for pain management in the ICU is typically by the IV route, regional approaches can offer advantages in selected cases.⁹ Options for regional anesthesia and analgesia (RAA) include continuous epidural analgesia (CEA) and anesthesia (central neuraxial techniques) and continuous peripheral nerve or plexus block. With medication delivery in close proximity to the spinal cord or nerves, these techniques can promote parenteral opioid sparing, which is associated with less respiratory depression and gastrointestinal hypomotility and conveys other benefits. However, these techniques introduce new issues related to needle and catheter placement and maintenance, as well as physiologic alterations related to local anesthetic block and epidural drug delivery. Critically ill patients are often at higher risk for complications due to coagulopathy, thrombocytopenia, sepsis, and hemodynamic instability. Peripheral nerve blocks are particularly useful for anatomically localized pain such as limb injury or operation. However, of all the various RAA techniques, the greatest experience in ICU patients is with CEA.

Similar to other pain management issues, there is more published research to support the use of RAA in noncritical care settings, and most ICU studies focus on patient who are postoperative or have sustained injury. The recent evidence-based review undertaken to develop the 2012 SCCM guidelines provides the most relevant and current basis for use of

Table 19.3 Common Opioid Medications

Drug	Metabolism	Onset/Duration	Dosing	Titration	Advantages	Disadvantages
Fentanyl	CYP3A4	1–2 min/2–4 hr (longer in liver failure)	<i>Bolus:</i> 25–50 µg IV push <i>Maintenance:</i> 12.5–200 µg/hr continuous infusion	Increase/decrease in increments of 25–50 µg every 5–30 min as needed; may be used to attain goal RASS or goal pain score	Less hypotension than with morphine; short-acting, less accumulation with organ dysfunction than with other opiates	CYP3A4 inhibitors may increase fentanyl effect; tolerance develops over time
Hydromorphone	Hepatic	5–10 min/2–4 hr (longer in liver failure)	<i>Bolus:</i> 1–4 mg IV push <i>Maintenance:</i> 0.25–50 mg/hr (no real maximum dose)	Increase/decrease in increments of 1–4 mg every 15–30 min as needed; may be used to attain goal RASS or goal pain score	May be preferred in patients with tachyphylaxis to fentanyl; does not accumulate with renal dysfunction like morphine	Long-acting and very potent
Morphine	Conjugation; active metabolites that undergo renal excretion	5–10 min/2–4 hr (longer in liver failure and ESRD)	<i>Bolus:</i> 2–4 mg IV push <i>Maintenance:</i> 0.5–49 mg/hr	Increase/decrease in increments of 1–4 mg every 15–30 min as needed; may be used to attain goal RASS or goal pain score	May be preferred in patients with tachyphylaxis to fentanyl	Accumulates with renal and hepatic dysfunction; hypotension due to histamine release
Remifentanyl	Plasma esterase	1–3 min/10–20 min	<i>Bolus:</i> 1 µg/kg over 1 min IV push <i>Maintenance:</i> 0.6–15 µg/kg/hr (use ideal body weight if more than 30% over ideal body weight)	Increase/decrease in increments of 1–2 µg/kg every 5–10 min as needed; may be used to attain goal RASS or goal pain score	No accumulation in hepatic or renal dysfunction	Can cause bradycardia and hypotension; may increase intracranial pressure

CYP3A4, cytochrome P-450 3A4; ESRD, end-stage renal disease; RASS, Richmond Agitation Sedation Scale.

Table 19.4 Common Opioid Adverse Effects

Potential Adverse Effect	Comment
Allergy	Rare; most common with morphine
Arrhythmias	QTc prolongation with methadone
CNS depression	Accumulation of active morphine metabolite in renal failure
Constipation	Start bowel regimen early if sustained opioid administration is likely Enteral naloxone is sometimes effective, but reverses analgesia
Cough	Most common with fentanyl and similar agents
Dry mouth	Use oral lubricants
Histamine release	Uncommon with fentanyl and similar agents Slow infusion rate Treat with combination of H ₁ and H ₂ agonists
Hyperalgesia	Paradoxical increase in pain sensitivity More common with short-acting opioids
Myoclonus	Consider reduced opioid dose or switch agent; hydrate
Nausea/vomiting	Administer antiemetic until tolerance develops
Neurotoxicity	Avoid meperidine—associated with highest incidence Can occur with morphine or hydromorphone, particularly at higher doses or in renal failure
Opioid dependency	Withdrawal symptoms can develop—usually coincide with clearance Prevent by tapering; reinstitute agent if withdrawal occurs
Pruritus	Consider naloxone, serotonic antagonists such as ondansetron
Rigidity	Most common with fentanyl and similar agents but can occur with any agent at high dose
Serotonin syndrome	Reported with meperidine and methadone Avoid concomitant serotonin reuptake inhibitor

CNS, central nervous system.

RAA in ICU patients.⁶ Specific patient populations were examined, and only thoracic epidural anesthesia/analgesia for postoperative analgesia in patients undergoing abdominal aortic surgery received a strong recommendation as a superior alternative to IV opioids.⁹² Interestingly, high-level evidence was also available to compare lumbar epidural analgesia to IV opioids in the same population and no

benefit was demonstrated.⁹³ Patients with traumatic rib fractures are the other population for which benefit from RAA was demonstrated for ICU patients. Specifically, use of thoracic epidural analgesia was associated with superior pain control and reduced incidence of pneumonia—but more hypotension—compared to parenteral opioids,^{94,95} and its use is supported as a weak recommendation in this setting.⁶ The evidence was insufficient to recommend thoracic epidural analgesia for intrathoracic or nonvascular abdominal surgical procedures.⁶ Similarly, the lack of high-quality research prevented a recommendation regarding the use of RAA for medical ICU patients.⁶

COMPLEMENTARY TECHNIQUES

Nonpharmacologic interventions such as music, relaxation, and provision of information can provide complementary pain relief and can be considered.^{9,55,96-98} However, although they are low cost, easy to provide, and safe, they have a relatively weak body of evidence to support their routine use, and they are not “high impact,” providing only limited opioid-sparing or pain intensity reduction capability.^{9,55,96}

SEDATION MANAGEMENT

Sedative drugs have formed the cornerstone for patient comfort and tolerance of the ICU environment for decades by calming anxiety, providing amnesia, and controlling agitation. There have been changing paradigms from preferential use of moderate- to long-acting benzodiazepines⁵ and acceptance of prolonged deep sedation a decade ago, to patient-focused sedation with careful monitoring, analgesia first, and more recently to an emphasis on the use of non-benzodiazepine sedative agents and using the lightest level of sedation possible.⁶ Management of sedation should be preceded by examining individual patient characteristics and effective pain control. It incorporates establishing the goals of sedative therapy, monitoring of the depth of sedation, selecting and administering the best agent(s) for the particular patient, and using protocolized management of sedation that includes structured elements to assure use of the lowest effective dose and lightest level of sedation. Common goals of therapy include relief of anxiety, control of frank agitation, promotion of patient-ventilator synchrony, and elimination of awareness when an NMBA is used. Monitoring of the depth of sedation is now routinely performed in most ICUs and is applied to titrate medications to a targeted level of consciousness and to avoid excessive or prolonged sedation.

Monitoring the depth of sedation is most commonly performed by observing patient behaviors, often after varying levels of stimulation, using a structured sedation scale.^{43,67,99} The domain being tested is that of arousal or level of consciousness and typically ranges from alert to comatose. Ramsay and coworkers developed the first widely utilized sedation scale for ICU patients—a 6-level scale based upon response to the assessor's voice and to physical stimulation.¹⁰⁰ Subsequent scale development has introduced assessment of agitation, ranging from calm to combative. Useful features of sedation-agitation scales include multidisciplinary development; ease of administration, recall, and

interpretation; well-defined discrete criteria for each level; sufficient sedation levels for effective drug titration; assessment of agitation; demonstration of good inter-rater reliability for relevant patient populations; and evidence of validity.⁴³ Recently the SCCM guideline task force performed a careful analysis of the sedation scales that have undergone validation analysis in ICU patients, including the Ramsay Sedation Scale (RSS),¹⁰⁰ the New Sheffield Sedation Scale,¹⁰¹ the Observer's Assessment of Alertness/Sedation Scale (OAA/S),¹⁰² the Sedation Intensive Care Score (SEDIC),¹⁰³ the Motor Activity Assessment Scale (MAAS),¹⁰⁴ the Adaptation to the Intensive Care Environment (ATICE) tool,¹⁰⁵ the Minnesota Sedation Assessment Tool (MSAT),¹⁰⁶ the Vancouver Interaction and Calmness Scale (VICS),¹⁰⁷ the Sedation Agitation Scale (SAS)¹⁰⁸ and the Richmond Agitation Sedation Scale (RASS).¹⁰⁹ Of these, the RASS had the highest total weighted psychometric score (19 of 20 possible points), followed by the SAS (16.5 points), and these two instruments are recommended in the 2012 SCCM guidelines as the most valid and reliable sedation assessment tools for measuring quality and depth of sedation in adult ICU

patients.⁶ The RASS, developed by a multidisciplinary group led by Sessler, is displayed in Table 19.5.¹⁰⁹ The RASS incorporates assessment of arousal in response to 2 levels of stimulation (voice, physical), presence or absence of cognition, sustainability of response, and the presence and intensity of agitated behavior into a 10-level scale subcategorized with positive (agitation) and negative (sedation) values.¹⁰⁹ The SAS, developed by Riker and colleagues, is displayed in Table 19.6.¹⁰⁸ Both RASS and SAS have been extensively tested for inter-rater reliability and validity in a cross section of ICU populations, correlated with subjective and objective measures of sedation, and evaluated for ease of use in clinical settings.^{6,67,108-112} The introduction of a sedation scale into clinical practice has been demonstrated to result in higher quality sedation with fewer hours of oversedation, as well as reduced utilization of sedative and analgesic drug doses, shorter duration of mechanical ventilation, and reduced use of vasopressors.^{113,114} Structured assessment and management of agitation and pain were similarly associated with less agitation, quicker extubation, and fewer nosocomial infections.¹¹⁵

Table 19.5 Richmond Agitation Sedation Scale (RASS)

Score	Term	Description
+4	Combative	Overtly combative or violent; immediate danger to staff
+3	Very agitated	Pulls on or removes tube(s) or catheter(s) or displays aggressive behavior toward staff
+2	Agitated	Frequent nonpurposeful movement or patient-ventilator dyssynchrony
+1	Restless	Anxious or apprehensive, but movements not aggressive or vigorous
0	Alert and calm	
-1	Drowsy	Not fully alert, but demonstrates sustained (>10 sec) awakening, with eye contact, to voice
-2	Light sedation	Briefly (<10 sec) awakens with eye contact to voice
-3	Moderate sedation	Any movement (but no eye contact) to voice
-4	Deep sedation	No response to voice, but any movement to physical stimulation
-5	Unarousable	No response to voice or physical stimulation

Performed using a series of steps: observation of behaviors (score +4 to 0), followed (if necessary) by assessment of response to voice (score -1 to -3), followed (if necessary) by assessment of response to physical stimulation such as shaking shoulder and then rubbing sternum if no response to shaking shoulder (score -4 to -5).

Table 19.6 Sedation Agitation Scale (SAS)

Score	Term	Description
7	Dangerous agitation	Pulling at endotracheal tube, trying to remove catheters, climbing over bedrail, striking at staff, thrashing side to side
6	Very agitated	Does not calm despite frequent verbal reminding of limits; requires physical restraints; biting endotracheal tube
5	Agitated	Anxious or mildly agitated; attempts to sit up; calms down to verbal instructions
4	Calm and cooperative	Calm, awakens easily, follows commands
3	Sedated	Difficult to arouse, awakens to verbal stimuli or gentle shaking but drifts off again, follows simple commands
2	Very sedated	Arouses to physical stimuli but does not communicate or follow commands; may move spontaneously
1	Unarousable	Minimal or no response to noxious stimuli; does not communicate or follow commands

Objective measures of cerebral function have been developed to quantify the level of consciousness as reflected by the cortical electrical activity based upon processed electroencephalographic (EEG) signals.^{67,116} Raw EEG signals are difficult to interpret, but proprietary mathematical algorithms have been developed and incorporated into commercially available devices to simplify interpretation of the power and frequency of the signal by converting this into a numerical display ranging from 0 (flat EEG) to 100 (fully alert). The Bispectral Index (BIS), Narcotrend Index (NI), Patient State Index (PSI), and State Entropy (SE) are examples of processed EEG monitors that have been used to assess level of consciousness in ICU patients.⁶ The addition of assessing the “evoked potential” to an auditory signal (i.e., auditory evoked potentials [AEPs])—displayed as the Auditory Evoked Response Index [AAI]) incorporates measurement of latency and amplitude of the evoked electrical potential.¹¹⁷ Collectively, these devices offer the advantage of continuous display of data, which can be used to rapidly detect unanticipated changes in level of consciousness, such as accidental cessation of propofol infusion.⁶⁷ However, validation studies of these objective tools against sedation scales and other parameters has yielded inconsistent results.^{6,67,118} A particularly challenging problem has been filtering out electromyographic (EMG) signals generated by activity of muscles of the head that lie between the brain and the EEG electrodes.¹¹⁹ Additionally, demonstration of added value to justify widespread use of this expensive monitoring technology when compared to routine sedation scale monitoring has been lacking in RCTs of ICU patients. Accordingly, the use of objective measures of brain function to assess the depth of sedation in noncomatose adult ICU patients who are not receiving NMBA is not recommended in the 2012 SCCM guidelines.⁶ There are unique clinical circumstances for which objective monitoring may be superior to routine clinical monitoring, including patients who are receiving NMBA and the guidance of titration of anticonvulsant medications to achieve burst suppression.⁶

SEDATIVE DRUG THERAPY

Sedative medications are widely used in the ICU setting and although various agents can be administered by other routes, most are given IV—either by continuous infusion or intermittent bolus. Traditionally, benzodiazepines have formed the cornerstone of ICU sedation,⁵ but recent clinical trial results and meta-analyses suggest that nonbenzodiazepines such as propofol and dexmedetomidine may be associated with better results such as less delirium and shorter ventilator time.⁶ Benzodiazepines activate γ -aminobutyric acid (GABA) A receptors, producing anxiolytic, amnesic, sedating, and hypnotic effects.^{6,120} Benzodiazepines cause respiratory depression and systemic hypotension—problems that are particularly prominent in the elderly. Although diazepam, midazolam, and lorazepam have been employed for ICU sedation over the years, diazepam is now used infrequently. Key pharmacokinetic and clinical features of midazolam and lorazepam are displayed in [Table 19.7](#). Delayed offset of action is relatively common with these drugs for a variety of reasons including tissue saturation after prolonged administration, impaired metabolism due to hepatic dysfunction, and in the case of midazolam,

accumulation of active renally cleared metabolites.^{6,120,121} Continuous infusion of lorazepam can lead to accumulation of the diluent vehicle, propylene glycol, causing toxicity that is characterized by metabolic acidosis and acute kidney injury, and accompanied by development of an increased osmolal gap.^{122,123}

Propofol is perhaps the most widely utilized agent administered for continuous IV sedation in the United States.¹²⁴ Propofol binds to GABA receptors as well as glycine, nicotinic, and muscarinic receptors producing effects similar to those from benzodiazepines.^{6,125} Like benzodiazepines, propofol has no analgesic effects. Propofol is highly lipid soluble, quickly crossing the blood-brain barrier and rapidly redistributing into peripheral tissues. These features result in rapid onset and offset of action (see [Table 19.7](#)). However, prolonged administration can result in tissue saturation that can ultimately produce delayed offset of action. Similar to benzodiazepines, propofol commonly causes respiratory depression as well as systemic hypotension. Because propofol is dissolved in a lipid emulsion, higher rates of propofol infusion can produce hypertriglyceridemia and acute pancreatitis. Each milliliter of propofol solution contains 1.1 kcal of nutrition, and thus an infusion rate of about 40 mL/hour results in more than 1000 kcal of nutrition in 24 hours. Propofol infusion syndrome (PRIS) is an uncommon complication that is typically associated with prolonged infusion of high-dose propofol (i.e., >70 μ g/kg/minute), although cases are reported at lower infusion rates or briefer administration. PRIS is characterized by metabolic acidosis, hypotension, cardiac arrhythmias, hypertriglyceridemia, and less commonly with acute kidney injury, rhabdomyolysis, liver dysfunction, and hyperkalemia.^{6,126,127}

Dexmedetomidine is a selective α_2 -receptor agonist with sedative properties similar to benzodiazepines and propofol, but has a number of unique features. In contrast to other sedatives, dexmedetomidine has analgesic properties and can be opioid-sparing; is sympatholytic, potentially producing prominent bradycardia as well as hypotension at higher doses; is associated with a more alert state relative to anxiolytic properties; and has minimal effect on respiratory drive.^{128,129} It does not bind GABA receptors. Selected pharmacokinetic and clinical characteristics are displayed in [Table 19.7](#). The most common adverse effects are hypotension and bradycardia. Hypotension can be particularly prominent when a loading dose is used—although hypertension can also occur. Clinical trial results suggest that when compared directly to midazolam, dexmedetomidine may be associated with lower prevalence of delirium.¹³⁰ The 2012 SCCM guidelines suggest that dexmedetomidine may be preferred over benzodiazepines in mechanically ventilated patients who have delirium and require continuous IV infusion of sedative medications.⁶

MANAGEMENT OF SEDATION

Sedative drug therapy is an important component of sedation and analgesia management as discussed earlier and outlined in [Box 19.2](#). Careful selection and titration of sedative drugs are critical to achieve optimal patient comfort while avoiding the adverse impact of excessive or unnecessarily prolonged sedation. The use of structured approaches to sedation and analgesia via algorithms and protocols has

Table 19.7 Common Sedative Medications

Drug	Metabolism	Onset/Duration	Dosing	Titration	Advantages	Disadvantages
Lorazepam	Conjugation to inactive metabolite	5-20 min/6-8 hr (duration prolonged in elderly or those with cirrhosis or ESRD to 48-72 hr)	<i>Bolus:</i> 2-4 mg IV push <i>Maintenance:</i> 2-6 mg IV/PO every 4-6 hr (preferred); infusion 0.25-20 mg/hr	Infusion: Increase/decrease in increments of 0.5-2 mg every 10-60 min to attain goal RASS score Increase/decrease in increments of 1-2 mg every 5-60 min to attain goal RASS score	Long half-life allows for intermittent dosing; less accumulation with renal/hepatic dysfunction Short-acting in patients with preserved organ function or with bolus dosing; fast onset	Propylene glycol toxicity in patients with renal failure; accumulation common with continuous infusion
Midazolam	Cytochrome P-450 3A4; active metabolite renally excreted	5-10 min/1-4 hr (accumulates in ESRD/CHF/liver failure)	<i>Bolus:</i> 2-4 g IV push <i>Maintenance:</i> 0.5-25 mg/hr	Increase/decrease in increments of 2.5-15 µg/kg/min every 1-15 min to attain goal RASS score	Short-acting in patients with preserved organ function or with bolus dosing; fast onset	CYP3A4 inhibitors may increase effect; accumulates with both renal and hepatic dysfunction; distributes to adipose tissue
Propofol	Conjugation	30-50 sec/3-10 min	<i>Maintenance:</i> 2.5-105 µg/kg/min	Increase/decrease in increments of 2.5-15 µg/kg/min every 1-15 min to attain goal RASS score	Short-acting; less delirium than with benzodiazepines	Hypotension, increased triglycerides, pancreatitis, propofol-related infusion syndrome, zinc depletion (with brand name only)
Dexmedetomidine	Hepatic via cytochrome P-450 and glucuronidation	Immediate onset only when bolus is given; ~3 hr to achieve full effect if bolus omitted/6 min (longer in liver failure)	<i>(Bolus:</i> 0.5-1 µg/kg, rarely given owing to hypotension/bradycardia) <i>Maintenance:</i> 0.2-1.5 µg/kg/hr	Increase by 0.1 µg/kg/hr no more often than every 30 minutes May titrate to effect (goal RASS score) OR until heart rate decreases by 10-20 beats/min Full effect will take ~3 hours to see If patient becomes hypotensive or bradycardic (HR <55), contact physician and stop infusion	Associated with less delirium than other agents; short-acting; little to no respiratory depression	Hypotension (especially with bolus dose and in fluid-resuscitated patients), bradycardia

CHF, congestive heart failure; ESRD, end-stage renal disease; HR, heart rate; RASS, Richmond Agitation Sedation Scale.

achieved a prominent place in ICU practice. There are several common themes. One theme is to tailor the sedation to the specific patient, including medication selection based upon sedation goals (such as rapid arousal), avoidance of side effects (such as hypotension), and consideration of elimination issues (such as avoiding midazolam in a patient with impaired renal function). Although all of the sedative drugs listed in Table 19.7 have a role in ICU sedation management, emerging evidence appears to favor using propofol or dexmedetomidine in preference to benzodiazepines in patients for whom continuous infusion sedation is needed—as suggested in the 2012 SCCM guidelines.⁶ A recent meta-analysis limited to moderate or high-quality RCTs demonstrated slightly longer ICU LOS with benzodiazepines, in comparison to propofol or dexmedetomidine.⁶ In a 2008 meta-analysis of 16 RCTs that compared propofol to alternative agents for moderate to long duration sedation (i.e., >2 days), propofol was associated with shorter duration of mechanical ventilation and shorter ICU LOS.¹³¹ In a 2010 meta-analysis of 24 RCTs comparing dexmedetomidine to alternative agents, ICU LOS was shorter with dexmedetomidine and duration of mechanical ventilation was not significantly different.¹³² Two recent studies deserve additional comment. A multicenter RCT comparing dexmedetomidine to midazolam by Riker and colleagues demonstrated that dexmedetomidine was associated with shorter time to extubation, lower prevalence of delirium, and fewer infections but no difference in ICU LOS, mortality rate, or sedation quality. Dexmedetomidine was less potent than midazolam and was associated with more bradycardia but less hypertension.¹³⁰ Jakob and coworkers recently reported two phase-3 multicenter RCTs that compared dexmedetomidine to midazolam and to propofol.¹³³ Patients randomized to dexmedetomidine had shorter duration of mechanical ventilation than with midazolam, but not with propofol. Patient interaction (communication, arousability, cooperation) was better with dexmedetomidine than with either other agent, but hypotension and bradycardia were more common.

A second major theme is to focus first on analgesia, as discussed earlier. The 2012 SCCM guidelines suggest that analgesia-first sedation be used in mechanically ventilated adult ICU patients.⁶ Asking first about pain, before the patient has been sedated and cognitively impaired, is advantageous. Additionally, several RCTs have demonstrated analgesia-based sedation to be associated with shorter duration of mechanical ventilation in comparison to hypnotic-based sedation.¹³⁴⁻¹³⁶ Finally, Strom and associates randomized mechanically ventilated adult ICU patients to bolus morphine (analgesia-based, limited sedation) versus morphine plus propofol for the first 48 hours, then midazolam (sedation + analgesia), and found shorter duration of mechanical ventilation and ICU LOS but threefold more agitation when sedative drugs were minimized.¹⁶

A third major theme is to strive for a light level of consciousness and to avoid accumulation of medications and their active metabolites, thus reducing the likelihood of delayed awakening. This approach is strongly recommended in the 2012 SCCM guidelines,⁶ based in part on studies like those of Strom and associates.¹⁶ The underlying rationale for this approach arises from the observation by Kollef and colleagues that use of continuous IV sedation and analgesia

is associated with delayed recovery from respiratory failure and longer LOS.¹³ Although a variety of sedation management strategies have been demonstrated to shorten the duration of mechanical ventilation, the most robust data support the use of a sedation protocol or the implementation of daily interruption of sedation.^{6,20} In an early RCT, Brook and coworkers found the use of a nurse-implemented protocol that emphasized intermittent therapy to be associated with shorter duration of mechanical ventilation, reduced ICU and hospital LOS, and fewer tracheostomies compared to usual management.¹⁴

The following year, Kress and colleagues showed in an RCT that daily interruption of IV sedation (DIS) until the patient was alert or agitated and then restarting the medications at 50% of the original dose was accompanied by more rapid recovery from respiratory failure, as well as performance of fewer tests for unexplained altered mental status.¹⁵ Interestingly, not all of the benefit could be attributable to reduced accumulation of medications or active metabolites because total propofol dosage was similar between groups although significantly less midazolam was used with daily interruption.¹⁵ This prompted speculation that the DIS might also permit earlier identification of sufficient respiratory reserve for ventilator weaning—“wake up and breathe.”¹³⁷ Girard and colleagues subsequently demonstrated that the strategy of combining DIS with performance of a spontaneous breathing trial (SBT) led to faster recovery from respiratory failure as well as reduced all-cause 1-year mortality rate compared to SBT alone.¹³⁸ Abrupt withdrawal of sedative (and sometimes analgesic) medications is accompanied by severalfold increases in circulating catecholamines as well as tachycardia and hypertension.⁴⁶ Experts have expressed concern that this unmasked stress response might be associated with cardiac ischemia.¹³⁹ In a prospective study, DIS was not accompanied by electrocardiographic or cardiac enzyme evidence of myocardial ischemia in at-risk patients.⁴⁶ Questions have also been raised as to potential impact of this abrupt withdrawal of medications designed to provide comfort on downstream neuropsychological disturbances such as posttraumatic stress disorder (PTSD).¹³⁹ An additional study by Kress and colleagues demonstrated no increase in subsequent PTSD and, actually, trends for better neuropsychological health months after daily interruption,¹⁴⁰ perhaps as a result of the added opportunities to establish concrete memories during awakening.¹⁴¹ There are populations for whom complete cessation of IV sedatives and analgesics is probably unwise. Girard and colleagues incorporated a safety screen into their protocol and avoid performing DIS in patients (a) receiving sedative infusion for active seizures or alcohol withdrawal, (b) receiving escalating doses due to ongoing agitation, (c) receiving NMBA, (d) having evidence of myocardial ischemia within the past 24 hours, or (e) having elevated ICP.¹³⁸ It may be that alcoholic patients are at particular risk for poor tolerance of daily interruption because patients randomized to this intervention had worse outcomes compared to a protocol approach in an RCT conducted in an ICU with a high prevalence of patients with alcohol use disorders.¹⁴²

A variety of other structured approaches have been examined in prospective trials, although many have utilized a less robust two-phase approach. Protocols that utilize an evidence-based nurse-implemented algorithm that seeks to

minimize medication doses has been linked to shorter duration of mechanical ventilation,¹⁴³⁻¹⁴⁸ shorter ICU and hospital LOS,^{144,147,148} lower direct drug costs,^{144,146} less opioid medication,¹⁴⁸ less medication-induced coma,¹⁴⁸ and lower 30-day mortality rate.¹⁴⁸ These interventions appear to be less effective in Australian ICUs, perhaps as a result of higher nurse:patient ratios.^{149,150} Other algorithms apply active pharmacist input,¹⁵¹ or focus on pain and agitation.¹¹⁵ There are few multicenter RCTs that compare several approaches—more are needed. In a preliminary study,¹⁵² Mehta and associates found DIS to be equivalent to a sedation protocol, setting the stage for a larger Canadian RCT. Carson and colleagues found continuous infusion propofol with DIS to be superior to intermittent lorazepam.¹⁵³

In summary, a variety of structured approaches to sedation management are effective for speeding recovery from respiratory failure and critical illness. Practical considerations for establishing a sedation protocol include multidisciplinary development, integrating published algorithms into the local environment, and sustaining a durable approach despite the challenges of insufficient time and resources.²⁰ Finally, emphasis on protocolized light sedation brings additional opportunities such as linkage to SBTs¹³⁸ and to early mobilization,¹⁵⁴ but new challenges such as managing patient agitation¹⁶ and consequences such as self-extubation.¹³⁸ The 2012 SCCM guidelines recommend using a multidisciplinary ICU team approach with provider education, preprinted protocols and order sets, and ICU rounds checklists to facilitate pain, agitation, and delirium management guidelines and protocols.⁶

NEUROMUSCULAR BLOCKING AGENTS

In contrast to analgesic and sedative medications, neuromuscular blocking agents (NMBAs) are administered relatively infrequently in the management of mechanically ventilated ICU patients. In an international study of mechanically ventilated patients, 13% of patients received NMBAs.¹⁵⁵ However, up to 55% of patients with ARDS in modern clinical trials receive an NMBA at some point in their management,¹⁵⁶ with even higher rates with interventions such as high-frequency oscillatory ventilation (HFOV).¹⁵⁷ The most common indication for an NMBA is to facilitate mechanical ventilation in particularly challenging scenarios such as severe status asthmaticus or ARDS. NMBAs can enhance oxygenation, reduce the risk of barotrauma, and improve synchronization of the patient and ventilator.^{30,158} Additional data suggest that pulmonary and systemic inflammation may be reduced, although the mechanism(s) are not established.¹⁵⁹ Indications for use of NMBAs include facilitation of mechanical ventilation, control of ICP, management of status epilepticus, reduction of oxygen consumption from muscle rigidity or shivering, the presence of an open surgical abdomen, prevention of lactic acidosis in conditions such as tetanus or neuroleptic malignant syndrome, and empirically in patients with severe ARDS ($\text{PaO}_2/\text{FiO}_2$ ratio < 120 mm Hg). Lacking robust RCTs, it is noteworthy that previously published guidelines assigned a grade of C (weak) for the recommendation to use an NMBA for these indications.³⁰ Most use of NMBAs is driven by improving control of a particular problem such as patient-ventilator

asynchrony or elevated ICP that persists despite use of less invasive measures.^{30,31,160} However, results of a 2010 multicenter RCT support the empiric administration of cisatracurium to all patients with fulminant ARDS ($\text{PaO}_2/\text{FiO}_2$ < 120 mm Hg) who do not have contraindications.³² The findings and limitations of this provocative study are discussed further.

COMPARISON OF AGENTS (TABLE 19.8)

The neuromuscular junction consists of a prejunctional motor nerve ending separated from a postjunctional membrane—or motor endplate—of skeletal muscle by a synaptic cleft. Acetylcholine (ACh) is released from vesicles in the prejunctional motor ending and bind nicotinic cholinergic receptors of the motor endplate, producing a change in membrane potential as a result of influx of sodium and efflux of potassium. Calcium is released from the sarcoplasmic reticulum, producing muscle action potential. Depolarizing NMBAs such as succinylcholine bind the receptors and cause the ion channel to remain open, producing depolarization and potentially causing sufficient potassium efflux to produce hyperkalemia. Additional depolarizations cannot occur until the agent diffuses from the receptors. Succinylcholine is the prototypical paralytic for rapid sequence intubation, due to its rapid onset and short duration of action.¹⁶¹ However, it can precipitate malignant hypertension and can cause hyperkalemia, which can lead to fatal arrhythmias.¹⁶² The cause of this adverse event is thought to be up-regulation of ACh receptors along the skeletal muscle membrane. Stimulation of these additional receptors by succinylcholine results in potassium efflux, leading to hyperkalemia. Hence, caution should be used when succinylcholine is considered for patients at risk for up-regulation of ACh receptors such as upper or lower motor denervation, chemical denervation (by muscle relaxants, drugs, or toxins), immobilization, infection, direct muscle trauma, muscle tumor, muscle inflammation, and burn injury. Furthermore, succinylcholine should be avoided in patients with renal dysfunction, as hyperkalemia is potentiated in this population. Additionally, succinylcholine has been associated with increases in intracranial and intraocular pressure and should be used with caution in patients with acute ocular or traumatic brain injury.¹⁶³

The nondepolarizing agents are bulky molecules with ACh-like moieties that bind the ACh receptors without ion flow or depolarization. Broadly, the nondepolarizing NMBAs are divided into two structural classes, aminosteroidal and benzyisoquinolinium agents. The aminosteroidal NMBAs incorporate an ACh-like structure onto a steroid backbone.¹⁶⁴ Much like other steroidal drugs, elimination of the aminosteroidal agents is organ dependent. Pancuronium, the first aminosteroidal NMBA, antagonizes not only nicotinic ACh receptors, but also muscarinic receptors.¹⁶⁵ This results in vagal blockade and tachycardia, making it less ideal for patients with significant cardiac disease.³⁰ Compared to other aminosteroidal NMBAs, pancuronium has a long half-life, which allows for sustained neuromuscular blockade to be achieved with intermittent bolus dosing.³⁰ Because of the long half-life, organ-dependent metabolism, and production of active metabolites, pancuronium has a high propensity to accumulate in critically ill patients.

Table 19.8 Properties of Neuromuscular Blocking Agents

Property	Atracurium	Cisatracurium	Pancuronium	Rocuronium	Succinylcholine	Vecuronium
Mechanism of action	Nondepolarizing Benzylisoquinolinium agent	Nondepolarizing Benzylisoquinolinium agent	Nondepolarizing Aminosteroidal agent	Nondepolarizing Aminosteroidal agent	Depolarizing Acetylcholine-like	Nondepolarizing Aminosteroidal agent
Onset	3-5 min	2-3 min	2-3 min	1-2 min	1-1.5 min	3-4 min
Duration	25-35 min	45-60 min	90-100 min	30 min	5-10 min	35-45 min
Renal elimination	<5%	<20% by renal and hepatic pathways combined	60-80%	30%	<10%	10-20%
Hepatic elimination	—	<20% by renal and hepatic pathways combined	15-40%	—	—	20-30%
Biliary excretion	—	—	5-10%	50%	—	40-75%
Hofmann elimination and ester hydrolysis	Yes	Yes	No	No	—	No
Plasma cholinesterase	No	No	No	No	Yes	No
Active metabolites	None (toxic metabolite laudanosine)	None	3-OH and 17-OH pancuronium	None	Succinylmonocholine (clinically insignificant depolarizing muscle relaxant properties)	3-Desacetylvecuronium
Bolus dosing	0.4-0.5 mg/kg	0.1-0.2 mg/kg	0.02-0.1 mg/kg	0.6-1 mg/kg	0.3-1.5 mg/kg	0.08-0.1 mg/kg
Continuous dosing	5-20 µg/kg/min	3 µg/kg/min (initial)	0.8-1.7 µg/kg/min	8-12 µg/kg/min	0.6-6 mg/kg/hr (not routinely recommended)	0.8-1.7 µg/kg/min
Histamine release	Yes (dose-dependent)	No	No	No	Yes	No
Vagal blockade	No	No	Yes	At higher doses	None (actually can cause bradycardia from vagal stimulation)	No
Prolonged blockade	Rare	Rare	Yes	No	Yes (in patients with reduced plasma cholinesterase activity)	Yes

Newer aminosteroidal NMBAs, such as vecuronium and rocuronium, offer advantages over pancuronium as they do not antagonize muscarinic receptors. Vecuronium is an intermediate-acting aminosteroidal NMBA with both renal and hepatic elimination. It offers utility both for procedural and sustained paralysis, but like pancuronium, can accumulate in patients with organ dysfunction. Rocuronium has the fastest onset and shortest duration of action of the aminosteroidal NMBAs, making it ideal for rapid sequence intubation in circumstances when succinylcholine is contraindicated. Like all aminosteroidal NMBAs, it exhibits organ dependent clearance; however, when used intermittently for procedural paralysis, this is rarely of clinical significance.

In contrast to the aminosteroidal NMBAs, benzylisoquinolinium agents are nonsteroidal agents that are degraded by plasma esterase and Hofmann degradation.^{164,165} Atracurium was the first benzylisoquinolinium NMBA and was advantageous in that it was an intermediate-acting paralytic with organ-independent clearance. However, atracurium causes significant histamine release and thus must be used with caution in patients with hypotension or shock. Additionally, patients with organ dysfunction are at increased risk of seizures when atracurium is used for sustained paralysis due to accumulation of a toxic metabolite, laudanosine.³¹ Cisatracurium is the cis-cis isomer of atracurium and represents approximately 15% of the atracurium conformation.¹⁶⁴ Like atracurium, cisatracurium undergoes clearance via plasma esterase and Hofmann degradation but is devoid of histamine release and toxic metabolites.

MONITORING

Monitoring of the patient during chemical paralysis is performed to ensure safety and effectiveness of the intervention. Goals of monitoring include achieving the targeted depth of sedation to accomplish therapeutic goals while reducing the likelihood of undesired prolonged paralysis or acute quadriplegic myopathy (AQM) and also avoiding other potential complications. Different targets for NMBAs may vary from merely reduced spontaneous movement or better synchronization of spontaneous breathing with mechanical ventilation to apnea for fully passive ventilation or complete cessation of all skeletal muscle activity. Accordingly, observation of limb and respiratory muscle activity as well as review of graphic display of ventilator data should be performed to confirm the therapeutic target is reached. Testing of deep tendon reflexes may be helpful as they disappear as 100% blockade is reached. Monitoring the depth and duration of paralysis is important in order to optimize neuromuscular blockade for each individual patient and to avoid complications of therapy.^{30,31,160,166} Such monitoring typically includes clinical evaluation as well as an objective measure of the extent of blockade using peripheral nerve stimulation (PNS) testing by evaluating the response to “train-of-four” (TOF) stimulation. In TOF testing, four equal brief electrical charges are delivered every 0.5 second from a nerve stimulator device that is attached to leads placed on the skin overlying a superficial nerve that innervates an easily observed muscle. The most common placement is over the ulnar nerve with observation of contraction of the adductor pollicis muscle or over the facial nerve with

observation of contraction of the orbicularis oculi muscle. It is estimated that if less than 75% of receptors are blocked, the four muscular contractions are equal in intensity and that once more than 90% of receptors are blocked no contractions occur. A common safety goal is for titration of the NMBA so that one to three muscle contractions are present, thus potentially avoiding excessive dosing. It is worth considering, however, that clinical effectiveness (such as patient-ventilator synchrony) is sometimes achieved while TOF reveals all four contractions. In contrast, in order to achieve apnea or complete cessation of muscular activity, TOF of zero may be necessary. In this circumstance, periodically decreasing the NMBA infusion rate until TOF of one or more may be necessary to avoid excessive dosing.

Despite the intuitive value of monitoring the depth of NMBA dosing, clinical trials that compare PNS monitoring to clinical monitoring alone have not consistently demonstrated added value. In one RCT, Rudis and coworkers demonstrated more rapid recovery to four of four TOF contractions and to spontaneous breathing as well as fewer episodes of delayed recovery when vecuronium infusion was titrated to achieve one of four TOF contractions in comparison to patients with clinical monitoring alone.¹⁶⁷ Patients with impaired renal function had the slowest recovery. In contrast, PNS monitoring did not lead to better outcomes in prospective trials of patients who received atracurium¹⁶⁸ or cisatracurium.¹⁶⁹ Further, intentional dosing of cisatracurium to achieve TOF of zero only marginally prolonged the recovery time.¹⁷⁰ Finally, no PNS monitoring was performed in the 2010 placebo-controlled RCT in which 178 patients received a 48-hour cisatracurium infusion and there was no difference in the rate of ICU paresis compared to the placebo group.³² Unfortunately, maintenance of TOF more than zero does not guarantee AQM will not occur. Most reported cases developed despite documented appropriate TOF results. Accordingly, although the 2002 SCCM guidelines recommended that all patients receiving NMBA should be assessed both clinically and by TOF monitoring (grade B recommendation) with a goal of adjusting the degree of NMBA to achieve 1 to 2 twitches (grade C recommendation), the validity of this recommendation is most compelling when vecuronium infusion is used but less so for atracurium or cisatracurium given subsequent published reports.³⁰ Monitoring of patients who are receiving NMBAs should also address prevention and early detection of venous thromboembolism (VTE), pressure ulcers, corneal ulcers, patient awareness, and inadequately controlled pain and anxiety.

COMPLICATIONS

The primary safety concerns with NMBAs are for prolonged paralysis due to persistent drug effect or from AQM. Both circumstances result in significant weakness and are considerations in the broad differential diagnosis of weakness in the ICU patient. Causes of weakness range widely from severe electrolyte disturbances like hypermagnesemia or hypophosphatemia to critical illness polyneuropathy, steroid myopathy, or Guillain-Barré syndrome. A variety of factors can increase the risk for prolonged recovery from NMBAs, including organ dysfunction and resulting impaired clearance of the parent compound, accumulation of active

Box 19.4 Drugs That Potentiate or Antagonize the Actions of Nondepolarizing Neuromuscular Blocking Agents (NMBAs)

Drugs That Potentiate the Action of Nondepolarizing NMBAs

Local anesthetics
Lidocaine
Antimicrobials (aminoglycosides, polymyxin B, clindamycin, tetracycline, vancomycin, amphotericin B, colistin)
Antiarrhythmics (procainamide, quinidine)
Magnesium
Calcium channel blockers
 β -Adrenergic blockers
Immunosuppressive agents (cyclophosphamide, cyclosporine)
Dantrolene
Diuretics (furosemide, bumetanide, ethacrynic acid)
Lithium carbonate
Corticosteroids
Inhaled anesthetics (enflurane, halothane, isoflurane, methoxyflurane, nitrous oxide)
Acetylcholinesterase inhibitors

Drugs That Antagonize the Actions of Nondepolarizing NMBAs

Phenytoin
Carbamazepine
Theophylline
Ranitidine

Modified from Murray MJ, Cowen J, DeBlock H, et al: Clinical practice guidelines for sustained neuromuscular blockade in the adult critically ill patient. *Crit Care Med* 2002;30(1):142-156; and Warr J, Thiboutot Z, Rose L, et al: Current therapeutic uses, pharmacology, and clinical considerations of neuromuscular blocking agents for critically ill adults. *Ann Pharmacother* 2011;45(9):1116-1126.

metabolites, drug-drug interactions, and other medical conditions. Drugs that potentiate or antagonize the actions of nondepolarizing NMBAs are listed in [Box 19.4](#). There is also considerable variability in duration of effect among NMBAs. The aminosteroids are eliminated by a combination of renal clearance and hepatic metabolism to a number of compounds, some of which are active and are eliminated in the urine. Accordingly, dysfunction of liver or kidneys is associated with prolonged paralysis.^{31,171} Resolution of paralysis is not predictable with vecuronium, particularly with prolonged infusion.^{171,172} This contrasts sharply with the benzylisoquinoliniums with recovery times of about 1 hour, even despite prolonged infusion¹⁶⁹ and with higher doses.¹⁷⁰ Perhaps most instructive is a prospective head-to-head comparison of vecuronium and cisatracurium in ICU patients in which average recovery time was fivefold longer with vecuronium.¹⁷³ Close monitoring of depth of sedation using TOF PNS appears to reduce the incidence of prolonged paralysis with vecuronium¹⁶⁷ but is of less certain value with atracurium or cisatracurium.^{168,169}

AQM is a potentially devastating form of NMBA-related weakness in which the muscle weakness can be severe and

quite protracted.³⁰ AQM is characterized by weakness of the limb and trunk muscles with sparing of the extraocular muscles as well as preserved sensory function and cognition. Understanding of the mechanisms underlying AQM have evolved from suspicion that myonecrosis alone was responsible to that of altered muscle membrane properties with loss of motor protein myosin and myosin-associated thick filament proteins. Work by Larsson and associates has demonstrated that a combination of myofibrillar protein degradation plus down-regulation of protein synthesis at the transcriptional level is prominent.¹⁷⁴ Key predisposing factors for ICU-acquired weakness appear to be functional denervation—such as from NMBAs and corticosteroids. The argument has been made that prolonged deep sedation may be another source of immobilization.³³ Additional risk factors for ICU-acquired polyneuropathy and myopathy include sepsis and other forms of systemic inflammation, hyperglycemia, malnutrition, and prolonged immobility. Although both aminosteroid and benzylisoquinolinium agents have been linked to AQM in case reports, it is noteworthy that in the relatively limited prospective clinical trial literature of NMBA in ICU patients, AQM is described in about 5% of patients who received vecuronium but none of the more than 200 patients who were administered atracurium or cisatracurium infusion.¹⁶⁹ Further, in the largest multicenter RCT of cisatracurium versus placebo, there was no difference in the incidence of ICU-acquired weakness.³² Finally, some experts consider the causality of NMBA—particularly short-duration NMBA—for producing ICU-acquired weakness to be far from certain.³³

EVOLVING ROLE IN ACUTE RESPIRATORY DISTRESS SYNDROME

NMBAs have been utilized for years to optimize gas exchange in patients with severe ARDS. Numerous RCTs demonstrate and other observational studies indicate that as many as one half of ARDS patients receive at least intermittent NMBA, with the most common indication being refractory hypoxemia. Sustained increases in $\text{PaO}_2\text{:FIO}_2$ ratio have been demonstrated in small RCTs.^{158,159} Interestingly, preliminary studies also have demonstrated lower levels of proinflammatory cytokines in bronchoalveolar lavage fluid and circulating blood in patients randomized to cisatracurium, in contrast to placebo.¹⁵⁹ In 2010, Papazian and coworkers published the results of a French multicenter RCT in which 340 patients with severe ARDS ($\text{PaO}_2\text{:FIO}_2 < 150$ mm Hg) were randomized to receive a 48-hour infusion of cisatracurium or placebo.³² Patients randomized to cisatracurium had better outcomes including lower rate of death at 28 days and trends for lower rates of death in the ICU and the hospital, more ventilator-free days and organ failure-free days, and fewer barotraumas. Post hoc analysis showed that the mortality rate benefit was limited entirely to the patients with most profound hypoxemia ($\text{PaO}_2\text{:FIO}_2 < 120$ mm Hg), although the relationship of other key outcomes to baseline oxygenation was not reported. Impressively, there was no difference in rates of ICU paresis, and limb weakness was identical for cisatracurium and placebo groups. A number of methodologic issues are worth noting, including no use of PNS for monitoring, use of very deep sedation (Ramsay Sedation Score = 6), use of ketamine for sedation in 20%

of patients, open label use of cisatracurium in 56% of placebo patients, the use of very modest PEEP despite severe hypoxemia, and the high barotrauma for placebo patients. Clinicians are eager for additional RCTs to confirm the findings.

SUMMARY AND CONCLUSIONS

The use of analgesic and sedative medications in the ICU setting is widespread and, although often viewed as a component of “supportive care” of critically ill patients, clearly can impact major outcomes. Accordingly, adopting a thoughtful, structured, and multidisciplinary approach to managing analgesia and sedation is important and centers around reasoned medication selection, close monitoring, and employing strategies to use the lowest effective dose. Similarly, NMBA administration can be of critical importance in managing selected clinical situations and should be guided by monitoring and limiting use to the shortest duration possible.

KEY POINTS

- A combination of non-pharmacological and pharmacological interventions can be useful to enhance tolerance of discomfort of invasive procedures, postoperative pain, and sleep deprivation common to the ICU experience.
- Adopting a patient-focused approach to managing sedation and analgesia that strives to minimize the depth and duration of reduced consciousness is associated with better outcomes.
- Development of delirium in the ICU is associated with worse outcomes, including impaired cognitive function after discharge.
- Agitated behavior is a common occurrence associated with adverse consequences including self-removal of critical tubes and lines and excessive adrenergic stress response.
- Identification of delirium or agitation should prompt a search for predisposing and precipitating medical conditions and medications.
- Self-reporting using standardized tools is the best method to detect and quantify pain; however, observation of characteristic behaviors can be helpful in the patient who is unable to self-report.
- Routine use of a validated sedation-agitation scale such as RASS or SAS promotes better communication, more precise sedative drug titration, and timely detection and grading of agitation.
- Recent research supports the use of non-benzodiazepines in preference to benzodiazepines when continuous infusion sedation is required.
- Targeting a more alert state for mechanically ventilated ICU patients is associated with better outcomes including shorter duration of mechanical ventilation, fewer tests, and shorter ICU length of stay.

KEY POINTS (Continued)

- Neuromuscular blocking agents (NMBAs) are administered infrequently to ICU patients, most often to facilitate the earlier stages of mechanical ventilation in severe ARDS or status asthmaticus.
- Safe and effective use of NMBA requires prevention of undetected pain and awareness in the paralyzed patient, prevention of adverse consequences of paralysis such as corneal damage or nerve injury from inappropriate positioning, prophylaxis against deep venous thrombosis, and monitoring to avoid excessive dosing.

PRINCIPLES OF THERAPEUTIC DRUG MONITORING

CONCLUSION

The pharmacologic effect of a drug is the result of complex interactions between its physiochemical characteristics and the biologic systems of the human body. The amount of drug given with each dose and the frequency of dosing are two of the most critical determinants of successful pharmacotherapy. Indeed, these factors are often the only differences between lifesaving effects and life-threatening toxicity. Dosing regimens are based on an understanding of these interactions and are designed to maximize the beneficial effects of drug exposure while minimizing risk of toxicity. When selecting a dosing regimen the clinician must be able to answer the following questions: What serum concentrations will be produced by the dose administered? How will the concentration change over time? Answers to these questions are provided by the science of pharmacokinetics (PK), which tells us what the body does to drugs: absorption, distribution, metabolism, and excretion. However, understanding PK alone is not sufficient to design optimal dosing regimens. Other important questions remain: What concentration is needed to produce the desired effect? What concentration has the potential to produce toxicity? These questions are answered by the science of pharmacodynamics (PD), the study of what drugs do to the body. Understanding PD allows the clinician to relate specific serum concentrations to pharmacologic effects. The use of both

pharmacokinetic and pharmacodynamic principles enables the clinician to maximize therapeutic efficacy while minimizing toxicity.

An additional level of complexity exists in critically ill patients. The majority of pharmacokinetic and pharmacodynamic information available has been obtained from studies in healthy volunteers and other non-critically ill populations. Critically ill patients differ from those often studied because they frequently experience hepatic and renal dysfunction, receive aggressive fluid resuscitation, and require vasoactive medications to maintain adequate organ perfusion. These physiologic alterations can dramatically alter dose response and vary greatly from patient to patient and even from day to day in the same patient. In addition, patients also frequently have significant comorbid conditions, such as chronic kidney disease, cirrhosis, and heart failure, which affect dose response.

GENERAL PHARMACOKINETIC PRINCIPLES

The pharmacokinetic profile of a drug is a mathematical model that describes the determinants of drug exposure. A complete model provides quantitative estimates of drug absorption, distribution, metabolism, and excretion after

Figure 20.1 Concentration vs. time curve following a single 200-mg intravenous dose of tobramycin in a 50-kg female. Note: Peak concentration determined by V_d and the size of dose given. Time course of elimination is determined by clearance and V_d . Approximately 90% of dose is eliminated after 5 half-lives.

Figure 20.2 Concentration vs. time curve demonstrating accumulation after repeated dosing of 750 mg vancomycin every 12 hours in a 50-kg patient. Note: Dosing regimens are based upon steady-state concentrations. Therapeutic drug monitoring should be conducted when regimens have reached steady state, which occurs after 5 to 7 half-lives.

single doses, in addition to the extent of serum and tissue accumulation after multiple doses. [Figure 20.1](#) depicts the concentration-time curve for a single intravenous (IV) dose of tobramycin. The curve allows for estimation of the maximum concentration achieved by the dose in addition to the time course of drug elimination. If dosing is repeated before elimination is complete, accumulation occurs and will continue until the system reaches “steady state,” at

which time the rate of administration is in equilibrium with the rate of elimination ([Fig. 20.2](#)). The definition of common PK terms can be found in [Table 20.1](#).

ABSORPTION

The first step in modeling exposure is to quantify the relationship between drug dosage administered and the amount

Table 20.1 Basic Pharmacokinetic Parameters

Parameter	Definition	Notes
Volume of distribution (Vd)	Dose (mg) $Vd = \text{peak concentration (mg/L)}$	Size of distribution compartment Quantifies the degree to which drug distributes into tissue
Area under the concentration-time curve (AUC)	Dose (mg/hour) $AUC = Cl \text{ (L/hour)}$	Total drug exposure produced by administered dose
Clearance (Cl)	Dose (mg/hour) $Cl = AUC \text{ (mg/L/hour)}$	Volume of blood cleared of drug per unit time
Elimination rate constant (Ke)	$Cl \text{ (L/hour)}$ $Ke = Vd \text{ (L)}$	The rate of drug elimination from the body per unit of time Relates clearance (liters cleared per hour) and Vd (volume to be cleared). This value is inversely related to drug half-life.
Bioavailability (F)	$AUC_{PO}/\text{dose}_{PO}$ $F = AUC_{IV}/\text{dose}_{IV}$	Percentage of dose that reaches systemic circulation Varies by route: Intravenous—100% Oral, subcutaneous, transdermal—variable: 0-100% Value expressed as a percentage of exposure relative to intravenous administration

of drug that reaches the systemic circulation. This relationship is known as the drug's bioavailability. IV administration provides 100% bioavailability, whereas this value can be considerably less for other routes. Oral ingestion is the most common route of administration in the general population and remains useful in many critically ill patients. Bioavailability through oral administration is usually less than 100% and is a function of two main factors: (1) absorption, which is the intrinsic ability of the drug to cross the gastrointestinal tract, and (2) presystemic metabolism, also known as the first-pass effect, which occurs primarily in the liver, and to a lesser extent in the intestinal lumen. Drugs that undergo extensive hepatic metabolism may have large first-pass effects and thus low bioavailability compared to IV administration. Similarly, drugs that are poorly absorbed will have low bioavailability.

Factors that determine absorption from the gastrointestinal (GI) tract include drug characteristics such as lipid solubility, ionization, and molecular size, in addition to physiologic factors such as gastric emptying rate, intestinal blood flow, motility, gastric and intestinal pH, gut wall permeability, and whether the dose is administered during the fasted or fed state.¹ Most drugs are orally absorbed through passive diffusion; although carrier-mediated absorption can also be important. The most important sites of absorption are the upper and lower segments of the small intestine.² The stomach regulates absorption through gastric emptying but is not an important site for absorption. Similarly, little drug absorption occurs in the colon with the exception of extended-release products.¹ Drugs with low oral bioavailability will require larger doses administered orally to produce equivalent exposure to that obtained from IV administration. Some drugs (e.g., vancomycin) have such poor bioavailability after oral administration that they cannot be used to treat the same disease processes as the IV formulations. Bioavailability is an important consideration when converting between oral and IV routes. For example, a patient who takes furosemide 80 mg orally at home would need only 40 mg given intravenously because this drug

has 50% bioavailability on average. Other routes of administration include subcutaneous (SC) and intramuscular injection, transdermal absorption, buccal absorption, and inhalation. Many drugs that are available as IV preparations are amenable to SC and intramuscular administration. However, some IV drugs have characteristics that preclude administration by routes other than large-bore catheters. These drugs include those with very basic or acidic pH, or those that act as vesicants and therefore need diluents added to maintain solubility. Drugs with adequate lipid solubility are amenable to transdermal and buccal administration.

DISTRIBUTION

After reaching the systemic circulation an administered dose then distributes throughout the body to produce a peak concentration. The relationship between the dose administered and the peak concentration observed after accounting for bioavailability is termed the *volume of distribution* (Vd). Vd estimates the size of the compartment into which the drug distributes. Total plasma volume in the average adult is 3 to 4 L.¹ However, the Vd for most drugs is much greater than this value. The discrepancy between plasma volume and a drug's Vd is accounted for by the extent that drugs concentrate in various tissues. The main determinants of Vd are the drug's lipid solubility, degree of protein binding, and extent of tissue binding.¹ High lipid solubility increases Vd through improved passage across cell membranes. Avid tissue binding also increases Vd as this concentrates drug outside the vascular space. Conversely, because only unbound drug can cross cell membranes and bind to tissue, high protein binding decreases Vd.

The simplest conceptualization of Vd is to view the body as a bucket—one large compartment where drug rapidly equilibrates between plasma and tissue and has uniform distribution (Fig. 20.3A). The one-compartment assumption is useful for drugs with small to intermediate Vds, such as aminoglycoside antibiotics, because these drugs have

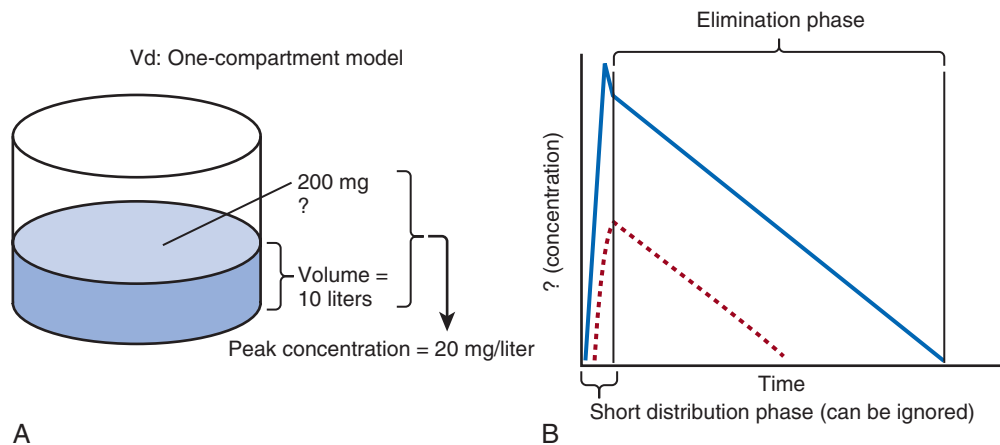

Figure 20.3 One-compartment model of drug distribution when drug rapidly distributes between plasma and tissue. **A**, Volume of distribution (Vd) defines the relationship between dose and peak concentration. **B**, Concentration vs. time curve for one-compartment model on a logarithmic scale. Solid line represents serum concentration. Dashed line represents tissue concentration. Note that tissue concentrations increase during the distribution phase. Because target receptors are frequently within tissues, the time course of the dashed line determines the onset and duration of effect.

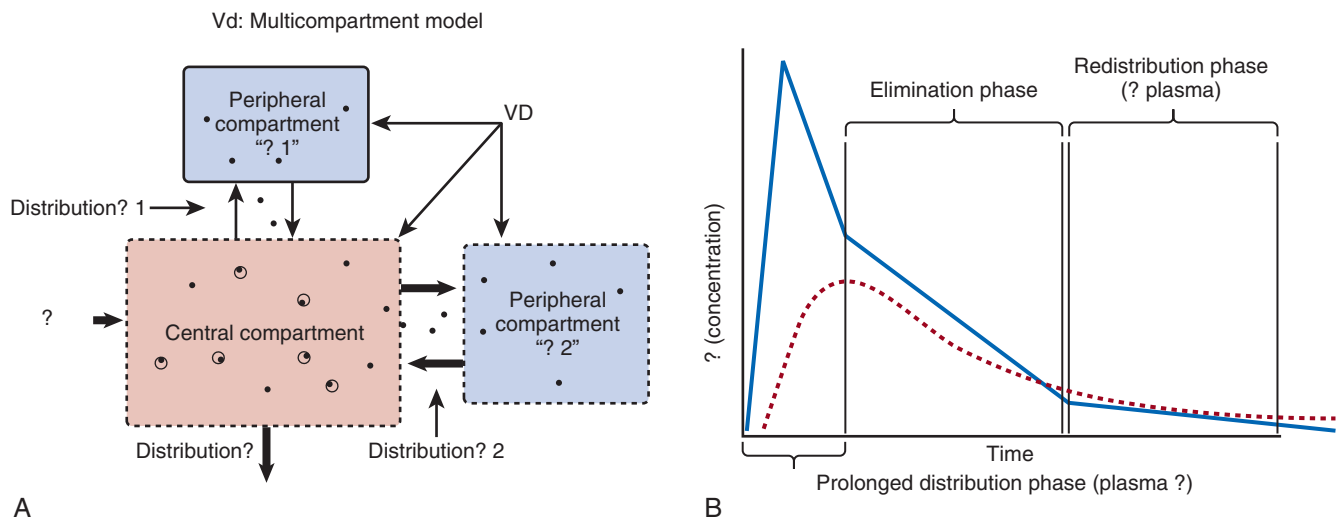

Figure 20.4 Multicompartment model of drug distribution when drug requires a longer period of time to achieve equilibrium between plasma and tissue. **A**, Depiction of a multicompartment model of volume of distribution (Vd). Drug enters the central compartment (serum) and then distributes into peripheral compartments (tissues). Total drug Vd is the sum of the individual compartments. Drug must then distribute back into serum to be eliminated. White circles represent serum protein molecules. Black circles represent drug molecules. **B**, Concentration vs. time curve for one-compartment model on a logarithmic scale. Solid line represents serum concentration. Dashed line represents tissue concentration. Note that tissue concentrations increase during the distribution phase. Large Vd drugs require prolonged distribution phases to saturate the peripheral compartments. The large Vd also results in a prolonged redistribution phase, which prolongs drug half-life.

a short distribution phase owing to their limited tissue penetration. Drugs with large Vds, such as fentanyl and amiodarone, require longer periods of time to achieve equilibrium between serum and tissue and thus have a prolonged distribution phase. As a result, the one-compartment assumption fails to accurately describe large Vd drugs. An alternative is to view the body as multiple compartments: a central compartment composed of blood, extracellular fluid, and highly perfused tissues; and one or more peripheral compartments composed of tissue beds with lower perfusion and drug binding affinity (Fig. 20.4A). The number of peripheral compartments required will be determined by the differential distribution rate in each tissue.

Two-compartment models adequately describe most large Vd drugs; however, a three-compartment model can be useful for agents that act in the central nervous system because of slower distribution as a result of the blood-brain barrier.

CLEARANCE

Drug elimination begins immediately upon entry into the body and can be divided into two main components: metabolism and excretion. Metabolism occurs mainly in the liver via enzymatic degradation, although it occurs to lesser extents in other tissues such as the kidney, lung, small

intestine and skin and via enzymes found in the serum. Nonenzymatic metabolism also occurs in the serum, as is the case for cisatracurium, which undergoes spontaneous degradation in the serum through ester hydrolysis. Excretion occurs primarily in the kidney, bile, and feces. Some drugs are eliminated predominantly by a single mechanism. For example, more than 95% of elimination for the aminoglycoside antibiotics occurs through excretion in the kidneys. Other drugs, such as ceftriaxone, are removed through multiple pathways. Regardless of pathway, the degree of protein binding exhibited by a drug is an important determinant of elimination rate, as only unbound drug can be eliminated from the serum.

The rate of drug removal via all routes of elimination is termed *clearance*, which is expressed as the volume of plasma cleared per unit of time. This value is assumed to be constant for most drugs. Defining total body clearance in terms of volume has important implications. If the *volume of blood cleared per unit of time* is constant, it then holds that the *amount of drug cleared per unit of time* must change in proportion to serum concentration. An increase in the rate of drug administration will lead to an increase in serum concentration, which in turn leads to commensurate increases in the rate of drug removal. Serum and tissue concentrations will accumulate until the rate of elimination is in equilibrium with the rate of administration, at which time the system is said to be at “steady state” (Figs. 20.2 and 20.5). Accumulation follows a linear pattern for most drugs, meaning that increases in dose are always matched by proportional increases in elimination, thus producing proportional

changes in serum concentration (see Fig. 20.5). Drugs that follow this pattern of accumulation are said to have first-order kinetics. However, some drugs exhibit saturable elimination. These drugs follow linear accumulation until the saturation point for elimination is reached. Once elimination is saturated, small changes in dose can produce substantial increases in concentration (see Fig. 20.5). Drugs that follow this pattern of accumulation have zero-order kinetics. Examples of drugs used in critically ill patients that have saturable elimination include phenytoin, heparin, propranolol, and verapamil.

HALF-LIFE

Once clearance is known the clinician can estimate the time needed for a given dose to be eliminated. Elimination time is commonly expressed in terms of half-life, which is the period of time required for the amount of drug to decrease by 50%. Half-life is calculated from the elimination rate constant:

$$k_e = \frac{\text{clearance (liters/hour)}}{\text{volume of distribution (liters)}}$$

k_e can be further transformed into half-life:

$$t_{1/2} = \frac{0.693}{k_e}$$

For any system that follows exponential decay, half-life can be used to estimate the amount of elimination that has occurred: after 5 half-lives more than 90% is eliminated.

Figure 20.5 Pharmacokinetic principle of linear and nonlinear drug elimination. **A**, Faucet and bucket representation of drug elimination. Faucet represents drug input rate. The channel in the side of the bucket represents drug elimination pathways. At steady state drug input is in equilibrium with drug elimination. **B**, The effect of a dose increase. On the right is an example of first-order kinetics. The channel allows for elimination to increase in proportion to the dose increase, producing proportional changes in drug level. On the left is an example of zero-order kinetics, in which elimination is constant after the saturation point. Here, the elimination channel is saturated at low input rates, producing a disproportionate increase in drug level.

Elimination approaches 100% after 7 half-lives. The time required for a dosing regimen to reach steady state is also an exponential function and thus can be estimated using half-life. This “5-7” rule of thumb is useful at the bedside. Dosing regimens approach maximal effects after 5-7 half-lives. Similarly, drug effects are usually completely dissipated after 5-7 half-lives. Using this rule, it can be predicted that drugs with long half-lives may take several days to produce target effects. This is less than ideal in the critically ill population when effective treatment is needed rapidly. As a result, loading doses are frequently used to hasten the time to steady state. Loading doses can be calculated by multiplying the target steady-state peak concentration by the patient's Vd. Recommendations for effective loading doses of most long half-life drugs are provided in the package labeling as applicable.

It is important to note that the time needed to eliminate a given dose is not only dependent on the clearance rate, but also on the drug's Vd. It is intuitive that half-life will be affected by changes in elimination pathways (e.g., renal failure). However, changes in Vd can have equally important effects on half-life, which can lead to higher than expected drug accumulation independent of changes in drug clearance. This effect has important implications for critically ill patients in whom Vd can be significantly altered.

MODELING THE CONCENTRATION-TIME CURVE

When estimations of bioavailability, Vd, and clearance are available, the concentration-time curve can be modeled. As discussed earlier, the one-compartment model is useful for hydrophilic drugs with small Vd. [Figure 20.3B](#) depicts serum concentration-time curve of a one-compartment model drug after IV administration plotted on a logarithmic scale. The initial peak concentration can be estimated using Vd and the size of the dose. The peak is followed by a short distribution phase, during which time drug is removed from the plasma through distribution to tissue in addition to being eliminated. After distribution is complete, the curve is defined by a second phase when drug is removed from plasma via elimination only. The time course of this phase can be estimated using half-life. The transition from distribution to elimination phase can be seen as a change in slope of the concentration curve. This is known as a bi-exponential pattern of decay. Because the distribution phase is short (usually 15-30 minutes) it can usually be ignored when performing calculations.

Conversely, large Vd drugs are more accurately represented using a two-compartment model ([Fig. 20.4B](#)). The important difference between one-compartment and two-compartment models is the significance of the distribution phase, which is much longer for drugs following a two-compartment model. As in the one-compartment model, the transition between distribution and elimination phases can be seen. However, a third phase is also evident near the end of the curve. This redistribution phase is a result of slow release of drug from the tissues back into the serum. This slow tissue release, known as the “context-sensitive half-life,” is responsible for the increased duration of pharmacologic effect seen after continuous infusions of highly lipophilic drugs such as fentanyl, midazolam, and propofol.

PHARMACODYNAMICS

As described in preceding sections, PK allows the clinician to estimate serum and tissue concentrations produced from dosing regimens. For example, a clinical pharmacist can use pharmacokinetic calculations to determine that 200 mg of tobramycin given as a 30-minute IV infusion will produce a peak concentration of 20 mg/L and will have an elimination half-life of 5 hours (see [Fig. 20.1](#)). Unfortunately, this information alone is not sufficient to guide dosing. From this example it is obvious that PK gives no information regarding whether these concentrations are appropriate. The clinician must still determine whether the peak concentration will be effective in treating the patient's infection while also determining the risk of nephrotoxicity associated with this level. This is when the study of pharmacodynamics (PD), which defines the relationship between drug concentration and effect, becomes important.

Although PD concepts are important for all dosing decisions, PD parameters have been best defined for antibiotics in part because the effect of interest (bacterial killing) can be readily measured through in vitro and in vivo studies. Therefore, the PD portion of this chapter will focus on antibiotics. However, the basic concepts can be applied to all drugs. Minimum inhibitory concentration (MIC) was the first PD parameter to show utility in predicting the effectiveness of antibiotic regimens. The MIC of an antibiotic is the minimum concentration needed to inhibit bacterial growth in vitro. It is intuitive from this that effective dosing regimens in humans would produce concentrations above this value. Less intuitive is determining how much higher the MIC concentrations need to be and for how long. Decades of research into these questions have elucidated additional PD parameters that help to optimize antibiotic dosing ([Fig. 20.6](#)). Interest in PD dose optimization has resurged in recent years in response to the convergence of increasingly drug-resistant bacteria with the lack of novel compounds in

PHARMACOKINETIC AND PHARMACODYNAMIC PARAMETERS ON A CONCENTRATION VS. TIME CURVE

Figure 20.6 Pharmacokinetic and pharmacodynamic parameters on a concentration vs. time curve. This figure depicts how drug concentration relates to bactericidal effect for various antimicrobial agents.

the drug development pipeline to treat these dangerous pathogens.³ Consequently, it is more important now than ever to maximize the effectiveness of the agents currently in use.

Two main factors determine the PD profile of an antibiotic: the dependence of effect on concentration and the persistence of effect after dosing. Antibiotics are first classified by the extent to which the rate of bacterial killing increases in response to increases in concentration. Some antibiotics show a robust dose response, whereas others do not. This relationship was elucidated in the neutropenic murine thigh infection model, when the effect of increasing antibiotic concentration on bacterial killing was examined.⁴ In repeated studies, the model showed that increasing concentration substantially increases both the magnitude (change from baseline) and the rate (change over time) of bacterial killing for aminoglycoside antibiotics such as tobramycin and the fluoroquinolone antibiotics such as ciprofloxacin. However, the same effects are not observed for the β -lactam classes of antibiotics. Although small concentration effects are observed in some models, the effect is saturated at a relatively low concentration (4-5 times the MIC). The difference in effect is related to the location of each agent's target receptor. Both aminoglycoside and fluoroquinolone antibiotics have receptor targets that are intracellular. Penetration of these antibiotics into the cell is enhanced by high concentrations. As a result, the activity of these agents can be predicted by the ratio of the peak concentration achieved by a given dose to the MIC of the organism. Accordingly, these agents are classified as concentration-dependent antibiotics. Conversely, β -lactams inhibit the formation of bacterial cell wall via inhibition of penicillin-binding protein (PBP). This protein is located on the bacterial cell surface, allowing effective binding at lower concentrations. In fact, *in vitro* analyses have shown that nearly all available PBP targets become saturated at concentrations that are four to five times the bacteria's MIC.⁵ Above this level, the action of β -lactams is relatively independent of concentration, making the duration of time that concentrations remain above the MIC the parameter most predictive of effect.

Another important observation from *in vitro* models is the persistent inhibition of bacterial growth after drug concentration falls below the MIC. This phenomenon, known as the postantibiotic effect (PAE), is common to all antibiotics, although the magnitude varies depending on the specific antibiotic and pathogen being analyzed. PAE is usually prolonged (3-6 hours) for agents that inhibit nucleic acid and protein synthesis such as the aminoglycosides.⁴ Most cell wall active agents such as the β -lactams have a short PAE for gram-positive bacteria and complete absence of PAE against gram-negative bacteria. As a result, bacterial regrowth occurs immediately as concentration falls below the MIC.⁴ Carbapenems are an exception to this as they are cell wall active agents and have a prolonged PAE.

Synthesis of these data allows antibiotics to be grouped according to their pattern of concentration dependence and persistent effects. The first pattern is that of concentration dependence combined with prolonged PAE. Activity of agents following this pattern is predicted by peak:MIC ratio and is optimized by giving large doses less frequently. The

second pattern is one of time dependence combined with short PAE. Activity of agents that follow this pattern is predicted by time above the MIC ($T > MIC$) and is optimized by giving smaller doses more frequently. A third pattern is that of concentration dependence with short PAE. The lack of significant PAE renders both peak:MIC and $T > MIC$ relationships as important predictors of effect. As a result, activity is best predicted by total antibiotic exposure and is quantified by the AUC:MIC ratio, where AUC is the area under the curve. The fourth and final pattern is one of time-dependent killing combined with moderate to prolonged PAE. The presence of PAE renders these agents less dependent on $T > MIC$, making AUC:MIC the most predictive parameter.

It is important to note that most PD analysis is based on total drug concentrations in the serum. However, only free drug concentrations that reach the site of action will affect bacterial killing. Thus, total drug concentrations in the serum may not always reflect antibiotic activity. This likely is not a concern for small Vd drugs with negligible protein binding, such as aminoglycoside and many β -lactams. These agents achieve rapid equilibration between serum and tissue and free concentrations are similar to total concentrations. However, total serum concentration may not be ideal for drugs with high protein binding or those with a large Vd. Tissue level analysis may offer better predictions for these drugs. However, owing to the greater difficulty in performing such analysis, their availability is limited.

β -LACTAMS

Alexander Fleming first discovered penicillin in 1928, marking the dawn of the antibiotic era. It was more than 2 decades later when Harry Eagle first noted that penicillin's effect could be modulated by dosing regimen. Specifically, he observed that penicillin's ability to kill bacteria was dependent on the amount of time that the drug was maintained at or above the bacteria's MIC.⁶ Later experiments confirmed time above MIC ($T > MIC$), as the PD index that predicts bacterial killing for penicillin and other β -lactam agents.⁴ The $T > MIC$ required for optimal response varies among the different β -lactams and is likely related to differences in the rate of bacterial killing and presence of PAE. Cephalosporins require the highest $T > MIC$ (50-70%), followed by the penicillins (30-50%) and the carbapenems (20-40%). The importance of $T > MIC$ has gained increasing attention in the last decade as a result of increasing bacterial resistance. Resistant bacteria have elevated MICs, making it more difficult to achieve adequate $T > MIC$ (Fig. 20.7). In addition, PK studies conducted in critically ill patients have shown that standard β -lactam dosing regimens may produce unacceptably low serum concentrations, resulting in diminished $T > MIC$.^{7,8} Although failure to achieve adequate $T > MIC$ has been shown to predict outcome in numerous animal models,⁹ there have been relatively few data in humans until recently. One study of patients with gram-negative bacteremia found mortality rates to double as the MIC increased from 4 mg/L to 8 mg/L in patients who were treated with cefepime.¹⁰ The importance of this finding is magnified when one considers that an MIC of 8 mg/L is considered to be within

Figure 20.7 Impact of increasing minimum inhibitory concentration on ability to achieve pharmacodynamic goals and impact of differing dosing regimens. Solid lines represent standard, short infusion administration. Dashed-dotted line represents extended infusion administration. Dashed line represents continuous infusion.

the susceptible range for cefepime. A similar increase in mortality rate was found in patients with bacteremia due to *Pseudomonas aeruginosa*: the relative risk of 30-day mortality was increased nearly fourfold when standard doses of piperacillin were used to treat isolates with elevated MICs to piperacillin.¹¹ Although serum concentrations were not measured in these studies, the data provide indirect evidence that links reduced $T > MIC$ to poor clinical outcome. In another study of gram-negative infection treated with cefepime, actual $T > MIC$ was calculated using serum concentration data. The study showed that likelihood of achieving bacterial eradication was significantly correlated with $T > MIC$.¹²

The inability to achieve adequate $T > MIC$ has led to the investigation of alternative dosing regimens. Simple dose escalation strategies are hampered by increasing the risk for toxicity. One alternative is to change the shape of the concentration-time curve using continuous or extended infusions. As seen in Figure 20.7, extending the infusion duration changes the shape of the concentration-time curve to promote longer $T > MIC$. Several PK studies have confirmed that these alternative dosing strategies can increase $T > MIC$ without increasing the size of the dose. One study found that $T > MIC$ following a 2-g dose of meropenem was increased 15% by extending the infusion duration from 0.5 hour to 3 hours.¹³ Although there are no outcome data in humans comparing extended infusions to continuous infusions, PK studies suggest a similar probability of target attainment.¹⁴

An additional theoretical consideration when comparing the extended and continuous strategies is the risk of selecting resistant bacteria. Mathematical modeling of bacterial growth dynamics suggests that a constant rate of bacterial killing creates more opportunity for generating resistant mutants than does a fluctuating kill rate.¹⁵ This effect has

been demonstrated in an in vitro model of ceftazidime continuous infusion, when maintenance of steady-state serum concentrations slightly above the bacteria's MIC resulted in the emergence of resistant bacteria subpopulations.¹⁶ This has led some investigator to recommend serum concentration monitoring if continuous infusions are used, with adjustment of the infusion rate to ensure steady-state concentrations are adequate.¹⁷ Although extended infusions produce more consistent concentrations compared to standard infusions, they produce greater fluctuation compared to continuous infusion. Extended infusions also possess the logistical advantage of less infusion time and therefore greater IV access. This is of particular benefit in patients who require multiple vasoactive and nutritional infusions.

Despite having sound PK/PD rationale, the clinical benefit of extended or continuous infusion strategies has yet to be documented in randomized clinical trials.¹⁸ Most available trials have important methodologic limitations. Although extended infusions increase $T > MIC$ compared to standard infusions, the benefit is of greatest importance for bacterial isolates with elevated MICs because standard doses already provide optimal $T > MIC$ when MIC is low. The benefit of extended infusions is also a function of the patient's renal function. Nicasio and associates recently found 3-hour infusions of cefepime increased $T > MIC$ compared to standard 0.5-hour infusions but the effect was limited to patients with preserved renal function (creatinine clearance [CrCl] 50-120 mL/minute).¹⁹ This effect modification is due to the prolonged half-life of cefepime in renal dysfunction, leading to higher trough concentrations and increased $T > MIC$. In light of these considerations, it is likely that the benefit of extended infusion strategies is greatest in patients with preserved renal function who are infected with high MIC pathogens, such as *P. aeruginosa* and *Acinetobacter baumannii*.

AMINOGLYCOSIDES

Aminoglycosides are broad-spectrum gram-negative agents that have been in clinical use since the 1960s. These agents quickly developed a reputation for having poor effectiveness and a high rate of nephrotoxicity compared to β -lactam agents. However, much of the initially dismal results observed with these agents are likely related to an inadequate knowledge of their PD profile. At the time, PD data available from β -lactam studies demonstrated $T > MIC$ to be the important factor predicting efficacy.⁶ As a result, early dosing strategies used small (1-2 mg/kg) doses given every 8 to 12 hours and little attention was paid to peak concentrations. The importance of achieving an adequate peak:MIC ratio was first described in patients by Moore and colleagues, who found that the likelihood of having a positive clinical response was greater than 90% when peak concentrations were 8 to 10 times the infecting organism's MIC.²⁰ A later study found that time to defervescence and normalization of leukocytosis was greater than 90% when peak:MIC ratio was 10 or greater.²¹ These data suggest that achieving high peak aminoglycoside concentrations is fundamental to successful treatment. In recognition of this, clinicians began to monitor peak aminoglycoside levels and adjust dosing regimens to ensure optimal peak:MIC ratios.

Aminoglycosides also exhibit a prolonged PAE. The duration of PAE in neutropenic animal models varies from 1 to 8 hours and is a function of the peak:MIC ratio.²² Higher ratios produce longer PAE. In addition, data suggest that PAE may be enhanced in patients with an intact immune system.⁴ Based on the combination of concentration-dependent activity and a prolonged PAE the efficacy of these agents could be maximized by giving large doses less frequently. This strategy is known as extended interval dosing (EID). Because aminoglycosides have short half-lives, the drugs are completely cleared from serum near the end of a 24-hour dosing interval in patients with normal renal function. Although the absence of drug may be concerning for the regrowth of bacteria, this is prevented by the PAE. In addition, a drug-free period near the end of the dosing interval minimizes the phenomenon known as adaptive resistance. Primarily described in *P. aeruginosa* infection, *adaptive resistance* refers to the diminished rate of bacterial killing after initial exposure to aminoglycosides.²³ This effect is caused by up-regulation of membrane-bound efflux pumps, which decrease the amount of drug that reaches the site of action inside the cell.²³ When the bacteria are free from drug exposure for a sufficient amount of time the adaptive resistance is lost and the bacteria will become fully sensitive again. Thus, in addition to achieving high peak:MIC ratios, EID may also allow for the reversion of adaptive resistance and greater bactericidal effect.

A wide variety of doses have been utilized in EID strategies. However, the most common are 5 to 7 mg/kg for gentamicin and tobramycin and 15 to 20 mg/kg for amikacin.²⁴ These doses were chosen based directly on PK/PD relationships. EID assumes that patients have a V_d that is within the normal range (0.25-0.3 L/kg). When given to patients who meet this assumption, the doses will produce peak concentrations that range from 16 to 24 mg/L and will achieve target peak:MIC ratios for isolates with an MIC up to 2 mg/L.²⁵ EID is also designed to achieve a drug-free

period of at least 4 hours at the end of the dosing interval.²⁵ Because aminoglycosides are cleared renally, dosing frequency is based on renal function assessment using estimated CrCl. To achieve an adequate drug-free interval, doses are given every 24 hours for patients with CrCl greater than 60 mL/minute, every 36 hours with CrCl 40 to 59 mL/minute, and every 48 hours with CrCl less than 40 mL/minute.²⁵ If aminoglycosides are used in renal dysfunction it is important that they still be dosed on weight owing to their peak:MIC dependent activity. EID of aminoglycosides has not been adequately studied in some patient populations (i.e., cystic fibrosis, thermal injury, pregnancy). The lack of validation data leads to the exclusion of these patients from EID nomograms, with the alternative being to use traditional dosing. However, based on our knowledge of the optimal PD parameter and the increased clearance seen in these populations, traditional dosing strategies may result in higher failure rates.

The benefit of EID has been studied in many small clinical trials and the results summarized in multiple meta-analyses. The conclusion from these studies is that EID produces similar efficacy to traditional dosing that is guided by close monitoring of peak concentrations.²⁶ However, most trials employed combination therapy with a β -lactam agent with activity against the infecting pathogen, potentially masking the effect of aminoglycoside dosing strategy.

As mentioned earlier, the use of aminoglycosides is limited by their propensity to induce nephrotoxicity. Nephrotoxicity is the result of accumulation in the epithelial cells of the proximal renal tubule. Of great importance is the fact that the rate of accumulation is saturable at relatively low concentrations in the tubule lumen.²⁷ This means that toxicity is not concentration dependent but rather time dependent. The implication is that high peak concentrations are just as safe as low peak concentrations. Once saturated, the rate-limiting step of tissue accumulation becomes the duration of exposure. Because EID produces a drug-free period near the end of the dosing interval, it reduces the amount of time drug can accumulate, potentially reducing toxicity. In vivo studies have confirmed that EID reduces renal accumulation.²⁸ It has been shown that a threshold of accumulation is needed before nephrotoxicity is produced and that this threshold is typically reached after 5 to 7 days of therapy.²⁹ Importantly, using EID prolongs the time to toxicity but the risk is not abolished. Once the duration of therapy exceeds 1 week, toxicity increases substantially regardless of dosing strategy. Duration of therapy was found to be a significant risk factor for toxicity in a cohort of elderly patients receiving once-daily aminoglycoside therapy.³⁰ The incidence of nephrotoxicity was only 3.9% in the 51 patients who received aminoglycoside therapy for less than 7 days compared to 30% in the 37 patients who received 8 to 14 days of therapy, and 50% of 8 patients receiving more than 14 days.

The aminoglycosides serve as a good example of how understanding PD principles can optimize the use of antibiotics. Concentration-dependent activity, prolonged PAE, adaptive resistance, and saturable renal accumulation characterize these agents. The use of EID takes best advantage of these characteristics. Regardless of dosing strategy, using the shortest duration of therapy possible is essential to minimizing the risk of toxicity.

VANCOMYCIN

Methicillin-resistant *Staphylococcus aureus* (MRSA) remains one of the most important pathogens causing infection in critically ill patients.³¹ Vancomycin has been the drug of choice for treating this pathogen for nearly 50 years. It inhibits cell wall formation in gram-positive bacteria in a similar fashion to the action of β -lactams. However, vancomycin binds a different receptor and produces a slower bactericidal effect. This slow bactericidal activity likely explains the slower symptom resolution and higher failure rates with vancomycin compared to β -lactams in the treatment of MRSA infections.³² The current breakpoint for vancomycin susceptibility against *Staphylococcus* species is an MIC of 2 mg/L.³³ In recent years, studies have identified MIC to be an important indicator of response to vancomycin therapy, which serves as a good example of how MIC can modify the ability of dosing regimens to achieve PD targets.³⁴

It was unclear for many years which PD parameter correlated best with vancomycin activity. Because vancomycin, like the β -lactams, inhibits cell wall formation, one might presume $T > MIC$ to be the best parameter. This assumption is supported by in vitro models showing that bacterial killing rate is concentration independent once above the MIC.³⁵ Other models show total drug exposure, as measured by the 24-hour AUC, to be more important for clinical response. In a study of patients with lower respiratory tract infection, Moise-Broder and coworkers found the AUC:MIC ratio to predict clinical response better than $T > MIC$.³⁶ They found a sevenfold increased probability of clinical cure and a decreased time to bacterial eradication when the AUC:MIC ratio was at least 400. No correlation with outcome was found for $T > MIC$. The discrepancy between vancomycin PD targets identified with in vitro models and human data underscores the importance of understanding the role of protein binding and tissue penetration. This is especially important for critically ill patients who can have altered tissue permeability and serum protein concentrations. Despite these limitations, total AUC:MIC ratio seems to be the best predictor of vancomycin activity and provides a parameter that can be easily monitored at the bedside.

Vancomycin dosing guidelines published in 2009 state that an AUC:MIC ratio of 400 or greater is the most appropriate PD target and that vancomycin trough concentrations should be monitored as a surrogate for AUC.³⁷ The guidelines recommend targeting steady-state trough concentrations of 15 to 20 mg/L for infections difficult to treat such as endocarditis, osteomyelitis, bacteremia, meningitis, and pneumonia. These troughs will achieve an AUC:MIC ratio of 400 or greater for pathogens with an MIC less than 1 mg/L. It is important to note that the success of this trough target is dependent on pathogen MIC. Mathematical simulations show that trough concentrations of 15 to 20 mg/L are unable to achieve target AUC:MIC ratios when the pathogen MIC is greater than 1 mg/L.³⁸ These simulations are supported by a recent meta-analysis that found a 64% relative increase in mortality risk when comparing high MIC (>1.5 mg/L) isolates to low MIC (<1.5 mg/L) isolates.³⁴ Although most MRSA isolates still have an MIC of 1 mg/L or less, many institutions have documented gradual increases in the number of isolates with MIC greater than 1 mg/L over the past decade.³⁹

MRSA isolates with a high MIC represent a currently unsolved therapeutic dilemma. An intuitive solution would be to increase target trough concentration in hopes of achieving target AUC:MIC. Steady-state troughs of 25 to 30 mg/L would reliably achieve AUC:MIC ratios greater than 400 against an MIC of 2 mg/L. This strategy would likely be unfeasible, however, as recent data have linked high troughs with increased risk of nephrotoxicity. One observational study showed the risk to increase when the initial trough concentration was greater than 20.⁴⁰ This finding is in agreement with data from a recent randomized clinical trial comparing vancomycin to linezolid for treatment of pneumonia.⁴¹ The rate of nephrotoxicity was increased in patients who receive vancomycin compared to linezolid (18.2% vs. 8.4%, respectively). In addition, a dose response was observed in the vancomycin arm: toxicity was observed in 37% of patients with initial trough greater than 20 mg/L, 22% when initial trough was 15 to 20 mg/L, and 18% when initial trough was less than 15 mg/L. Although these data use trough concentration to assess the dose:response relationship, trough is closely correlated with peak concentration and total AUC. Consequently, it is unclear which parameter is most closely associated with toxicity. An observational study showed continuous IV (CIV) infusions of vancomycin to have a slower rate of onset of nephrotoxicity compared to intermittent IV (IIV) infusion despite having similar cumulative doses in the two groups.⁴² This study suggests that toxicity may be related to high peak concentrations, although more data are needed to verify these findings. The only randomized clinical trial to date of this strategy found no difference in safety or efficacy of continuous versus intermittent IV vancomycin.⁴³ Consequently, until more data are available, targeting troughs above 15 to 20 mg/L or the use of high-dose CIV infusions cannot be recommended.

Another option for treating high MIC isolates is to use alternative agents with activity against MRSA (i.e., linezolid, daptomycin, telavancin, and ceftibiprole). However, to date no agent has definitively been shown to provide improved outcome compared to vancomycin in the general treatment of MRSA. Additionally, few data are available that compare agents specifically in patients with high MIC isolates, and cross-resistance between vancomycin and alternative agents has been noted.⁴⁴

THE EFFECT OF CRITICAL ILLNESS ON PHARMACOKINETICS AND PHARMACODYNAMICS

Understanding the basic concepts of PK and PD is essential to providing safe and effective drug therapy. However, the physiologic derangements found in critically ill patients can significantly alter PK/PD relationships, which can lead to both exaggerated and diminished pharmacologic response with standard dosing regimens. Consequently, the ICU clinician must integrate a thorough understanding of critical illness physiology with PK/PD principles to provide appropriate drug therapy. A summary of these changes can be found in [Table 20.2](#).

The systemic inflammatory response syndrome (SIRS) is present to some degree in nearly all critically ill patients.

Table 20.2 Pharmacokinetic Changes during Critical Illness

Parameter	Relevant Critical Illness Physiology	Effect on Pharmacokinetics
Absorption	Reduced mesenteric and subcutaneous blood flow during shock Delayed gastric emptying Reduced GI motility	Reduced peak concentration and AUC Delayed onset of effect Variable
Distribution	Capillary leak and fluid resuscitation Reduced albumin concentration Increased AAG concentration Decreased tissue binding	Increased Vd for hydrophilic drugs Increased Vd for drugs highly bound to albumin Decreased Vd for drugs highly bound to AAG Decreased tissue binding
Clearance	SIRS response producing increased blood flow to liver and kidneys Acute kidney injury and acute liver injury Reduced albumin concentration Increased AAG concentration	Increased drug clearance Decreased drug clearance Increased drug clearance for drugs highly bound to albumin Decreased clearance for drugs highly bound to AAG

AAG, α_1 -acid glycoprotein; AUC, area under the curve; GI, gastrointestinal; SIRS, severe inflammatory response syndrome; Vd, volume of distribution.

Common insults such as sepsis, trauma, surgery, the acute respiratory distress syndrome, and pancreatitis all produce SIRS. Salient features of SIRS are increased heart rate, decreased arterial vascular tone, and increased vascular membrane permeability.⁴⁵ Without adequate fluid resuscitation the result is low intravascular volume, inadequate preload, and subsequent low cardiac output. As a result, blood flow to organs such as the liver and kidneys can be compromised, leading to decreased drug clearance and serum and tissue accumulation. This physiology is commonly seen in patients admitted with sepsis when adequate resuscitation has not yet occurred. Fluid resuscitation restores preload and increases cardiac output. Because of increased heart rate and low systemic vascular resistance, patients with resuscitated SIRS or sepsis frequently have hyperdynamic physiology in which organ blood flow can be higher than normal.⁴⁶ Consequently, drug clearance will also be higher than normal. This change is of special concern in patients with sepsis as it may lead to increased antibiotic clearance, suboptimal PD achievement, and worse treatment response.⁴⁷ Low serum levels of cephalosporin antibiotics have been documented in septic patients given standard doses.⁷ In addition, the need for increased dosing frequency has been documented for trauma patients treated with vancomycin.⁴⁸ Although there are no clinical trial data examining this issue, there is a physiologic rationale to administer higher doses or extended infusions of β -lactams and other renally cleared drugs to patients with hyperdynamic physiology.⁴⁷ This is likely most pertinent during the first 48 to 72 hours of treatment for patients with sepsis. Importantly, sepsis also frequently leads to organ dysfunction including acute liver and kidney injury. As a result, dosing decisions need to be reassessed daily. Careful assessment of renal and hepatic clearance is required and must be combined with prudent judgment of the risk-benefit ratio of each individual drug. Clinicians may err on the aggressive side of dosing decisions for drugs with a wide therapeutic index such as the β -lactam antibiotics. Conversely, the risk-benefit ratio may support more conservative

dosing decisions for drugs that have serious dose-related toxicity such as antiarrhythmic agents and anticoagulants.

The amount of fluid resuscitation required to maintain intravascular volume in patients with SIRS can be significant. Early goal-directed therapy of sepsis frequently results in patients having a net gain of more than 10 L of fluid during treatment.⁴⁹ Significant increases in fluid balance are not limited to sepsis, but are also found in postsurgical patients, trauma patients, and patients with ARDS.^{50,51} These changes in fluid balance combined with the capillary leaks produced by SIRS can have significant effects on the Vd of hydrophilic drugs. The aminoglycoside antibiotics serve as a prototypical example. The average Vd of aminoglycosides is 0.25 L/kg in non-critically ill patients.⁵² This value is compared to an average of 0.36 L/kg in general surgical and 0.75 L/kg in medical ICU populations, respectively.^{53,54} In addition to being significantly increased, there can be a great deal of variability in Vd among patients. In a general surgical population aminoglycoside Vd has been reported to range from 0.14 L/kg to 0.67 L/kg. These increases in Vd result in decreased peak concentrations with a given dose. Owing to the linear kinetics of aminoglycosides a doubling of Vd will decrease peak concentration by one half. Thus, in EID of tobramycin a typical 5 mg/kg dose in a patient with a Vd of 0.25 L/kg would result in a peak of 20 mg/L, although a patient with a Vd of 0.5 L/kg would have a peak of 10 mg/L. The patient with the smaller Vd (0.25 L/kg) would achieve the target peak:MIC ratio of 10 for treatment of a *Pseudomonas aeruginosa* isolate with an MIC of 2 mg/L. However, the patient with the Vd of 0.5 L/kg would achieve a suboptimal peak:MIC ratio of 5.

A seemingly obvious solution to the previous dilemma would be to administer 10 mg/kg of tobramycin to the patient with a larger Vd. Indeed, this would achieve a peak of 20 mg/L and target peak:MIC ratio. However, there is an additional consequence of increased Vd that limits the feasibility of dose escalation. As discussed earlier in the PK section, drug half-life is a function of both clearance and Vd. Thus, increases in Vd also increase half-life.

Consequently, the time required to clear a given dose will be increased *independent of clearance*. Again, because aminoglycoside PK is linear, a doubling of V_d results in a doubling of half-life. Failure to recognize the effect of V_d on half-life would lead the ICU clinician to choose an incorrect dosing interval, which would lead to excess drug accumulation and toxicity. Although the consequences of V_d on peak concentration and half-life are readily apparent for the aminoglycoside antibiotics, it is an important consideration for all drugs used in critically ill patients.

In addition to changes in organ blood flow and volume status, critically ill patients also have altered serum protein concentrations, which can have important effects on drugs that are highly protein bound. The two most important serum proteins that contribute to drug binding are albumin, which binds mostly to acidic drugs, and α_1 -acid glycoprotein (AAG), which binds mostly to basic drugs. A variety of factors contribute to altered serum protein concentration, including malnutrition, hemodilution, and the acute phase response.⁵⁵ Interestingly, the acute phase response has a variable effect on these proteins: albumin decreases while AAG increases.⁵⁶ A change in serum protein concentration alters the unbound fraction of drug in the serum. Determination of the effects of altered free drug fraction requires consideration of the following: only the free fraction produces pharmacologic effects; only the free fraction is available to distribute into tissues; and only the free fraction is available to be cleared from the body. Increased free fraction produces increased V_d and clearance. The net effect of these changes is a lower total serum concentration with relatively unchanged absolute free concentration.⁵⁷ Because only free drug concentration can bind to target receptors, the change in protein binding *does not* alter pharmacologic response. As a result, dose adjustments are unnecessary. This is the case for most drugs that are highly protein bound. However, there is a short list of drugs for which changes in protein binding can produce clinically important changes when the drugs are given IV. Such drugs have a high extraction ratio (see discussion under “[Hepatic Disease](#)”) and a narrow therapeutic index.⁵⁷ Examples relevant to ICU practice include midazolam, haloperidol, fentanyl, lidocaine, milrinone, diltiazem, and nicardipine. Decreased serum protein concentration can result in exaggerated free drug exposure, prolonged duration of effect, and increased risk of adverse events. Increased serum protein concentration would produce the opposite: reduced free drug exposure with possible inadequate response. This result would be important for drugs highly bound to AAG, such as lidocaine.⁵⁶ Unfortunately, there are few data available in critically ill patients that examine the effect of altered protein binding on PK/PD relationships in critically ill patients.

It is perhaps most important to consider the effects of altered protein concentration when monitoring serum concentrations to guide dosing decisions. As described earlier, altered protein binding changes the relationship between *total serum concentration* and pharmacologic effect, although the relationship between *free drug concentration* and effect frequently remains unchanged. As a result, using total serum concentration to guide dosing in critically ill patients can lead to erroneous dose adjustments and potential

toxicity or therapeutic failure. Although the use of free drug concentration monitoring has been limited mostly to the antiepileptic phenytoin, it may also be useful for other highly protein bound drugs classes, including immunosuppressants and antibiotics.⁵⁷⁻⁵⁹

SPECIAL CONSIDERATIONS REGARDING ROUTES OF ADMINISTRATION

Although oral administration is useful in critically ill patients, the route may not always be appropriate. Physiologic changes such as decreased mesenteric blood flow, altered GI motility, gastric acid suppression, and gut wall edema can alter the rate and extent of absorption from the GI tract.⁶⁰ The hemodynamic response to hypotension involves shunting blood flow away from mesenteric circulation, substantially limiting a drug's access to the systemic circulation.⁶¹ Hepatic blood flow may be preserved in the short term owing to the “hepatic buffer” response but is often decreased with prolonged states of low systemic perfusion.⁶² Low hepatic blood flow will limit hepatic metabolism and result in increased bioavailability of drugs with a large first-pass effect. The net effect of these derangements can be highly unpredictable but often lead to diminished bioavailability. Slow gastric emptying, which occurs in 50% to 60% of critically ill patients, delays the onset of absorption and often results in lower peak serum concentrations.^{63,64} Despite these changes, the overall exposure as measured by the AUC is not significantly different compared to healthy volunteers.⁶⁵ Impaired small intestine motility also slows the rate of absorption. However, because residence time in the GI tract will be increased, bioavailability may actually increase for poorly absorbable drugs such as furosemide and ampicillin.⁵ Carrier-mediated absorption may be limited independent of changes in motility or blood flow as a result of dysfunctional membrane transporters.

There are limited data that describe the effectiveness of oral administration in critically ill patients. Some studies, conducted in patients tolerating enteral feeding, show absorption to be adequate for drugs with normally high bioavailability such as fluconazole and ciprofloxacin.^{66,67} However, other studies show unpredictable and sometimes inadequate absorption.⁶⁸ Given this variability and the absence of a useful parameter to monitor GI function at the bedside, the IV route is preferred in patients with hemodynamic instability. The oral route should be reserved for patients who are clinically stable and tolerating enteral feeding. When transitioning medications from IV to oral, it is helpful to begin with agents that have easily measurable effects, such as cardiovascular agents.

The SC route is also used in critically ill patients, most commonly for insulin administration and pharmacologic venous thromboembolism (VTE) prophylaxis. Unfortunately, few studies examine the PK of SC administration in critically ill patients. The available data are limited to a few small studies of the low-molecular-weight heparins. Dorffler-Melly and associates compared anti-factor Xa activity produced by prophylactic doses of enoxaparin in three groups: non-ICU patients, ICU patients, and ICU patients receiving vasopressors. Peak anti-factor Xa activity was decreased by

60% in patients receiving vasopressors.⁶⁹ In another study, only 28% of patients on vasopressors achieved the target anti-factor Xa level after receiving 3000 IU of certoparin daily.⁷⁰ Although these data are provocative, the clinical importance of low anti-factor Xa levels is unclear. Some reports have correlated low levels with thrombosis, whereas others have not.^{71,72} Despite this uncertainty, recent investigations have begun to examine the effect of higher doses and use of the IV route for VTE prophylaxis.^{73,74} Not surprisingly, the data show that increased doses lead to increased drug exposure and higher anti-factor Xa levels. Although higher levels may decrease thrombosis risk, they may also increase bleeding risk. As such, outcome data from large clinical trials are needed before such strategies can be recommended.

DRUG-DOSING CONSIDERATIONS IN SELECT CRITICAL CARE POPULATIONS

RENAL DISEASE

Acute kidney injury (AKI) is a common occurrence in the ICU. Using a consensus definition, rates of AKI range from 10% to 30% in the general ICU population, and 40% to 60% in patients with severe sepsis and septic shock. In addition, approximately 5% will require some form of hemodialysis.⁷⁵ This frequency is an important concern for drug dosing because renal elimination is one of the two primary routes of drug clearance. Therefore, it is important for ICU practitioners to understand the basic approach to renal drug dosing.

ASSESSING RENAL FUNCTION

Accurate assessment of renal function is imperative to make appropriate dosing decisions. This assessment may include a measurement or estimate of the glomerular filtration rate (GFR). Inulin is the gold standard for the assessment of renal function.⁷⁶ However, owing to limited availability and high cost, it is rarely used outside a research setting. In its place creatinine is frequently used as a marker for renal

function as it is produced at a fairly constant rate and is largely removed by glomerular filtration. The most reliable method that employs creatinine is via a timed urine creatinine collection. A 24-hour collection is ideal to account for changes that may occur in volume status, hemodynamics, or organ function throughout the day. However, a 24-hour collection period has multiple opportunities for error and is often impractical because a practitioner must wait longer than 24 hours to assess a patient's renal clearance. As a result, shorter durations of collection have been examined. Unfortunately, the results are varied, with some investigators demonstrating poor correlation with collections less than 8 hours and others showing good correlation with collections as short as 2 hours.^{77,78} Consequently, the ideal duration of collection is unclear. In addition, it is important to note that timed urine collections are not free from bias in critically ill patients. One report found both a 30-minute and 24-hour urine creatinine collection to be significantly biased compared to inulin clearance.⁷⁹ Despite this limitation direct measurement of urine creatinine can still be useful to make dosing decisions in patients who are receiving narrow therapeutic index drugs or are at the extremes of age or weight.

Although direct measurement is ideal, most practitioners use equations to estimate renal clearance due to inherent limitations in the collection process. Equations exist to estimate both the GFR and also CrCl. Table 20.3 lists the two most commonly used equations and considerations for their use.⁸⁰⁻⁸² There has been much clinical debate as to the optimal equation to use for drug dosing. Historically the most frequently used method has been the Cockcroft-Gault (CG) equation, which provides an estimate of CrCl. This choice is primarily due to the fact that most available dosing recommendations are based on PK studies that estimated renal function with the CG equation.⁸³ More recently, the Modification of Diet in Renal Disease (MDRD) equation has become widely used clinically as an estimate of GFR. It has been primarily used for staging of kidney disease, and at one time recommendations were to avoid using it for drug dosing. This proscription was largely based on the fact that numerous studies have compared the CG and MDRD

Table 20.3 Commonly Used Equations to Estimate Renal Clearance

Equation	Estimated Parameter (units)	Formula	Considerations
Cockcroft-Gault	CrCl (mL/min)	$(140 - \text{age}) \text{ BW} / (\text{SCr} \cdot 72) \cdot (0.85 \text{ if female})$	Inaccurate in patients with acutely changing renal function Ideal weight parameter is controversial in obese patients
Reexpressed MDRD (four-variable)	GFR (mL/min/1.73 m ²)	$175 \cdot \text{SCr}^{-1.154} \cdot \text{age}^{-0.203} \cdot (0.742 \text{ if female}) \cdot (1.21 \text{ if AA})$	Inaccurate in patients with acutely changing renal function Must be individualized for body surface area by multiplying estimated GFR \times (estimated BSA/1.73 m ²) Little information available in obese, elderly, or hepatic disease patients

AA, African American; BSA, body surface area; BW, body weight (in kg); CrCl, creatinine clearance; GFR, glomerular filtration rate; MDRD, Modification of Diet in Renal Disease [Study]; SCr, serum creatinine.

equations and have shown discordance between drug-dosing recommendations derived from the two equations.⁸² Despite these data, in 2009 the National Kidney Disease Education Program suggested that either equation could be used for drug dosing purposes.⁸³ Many practitioners continue to use the CG equation because of its ease of use, because of its familiarity, and because many dosing recommendations were derived from this equation. Several other less frequently used equations to estimate CrCl or GFR can be found in more detailed reviews on estimating renal clearance.⁷⁶

Regardless of which approach to renal function assessment is used, it is important to remember that all have limitations. Because changes in serum creatinine are delayed in comparison to changes in actual renal function, calculations based on this marker will be unreliable in rapidly changing renal function. These equations will overestimate renal function when creatinine is increasing and may underestimate renal function when creatinine is decreasing. Other patient populations that require specific considerations are patients at the extremes of weight and elderly patients. Both CG and MDRD equations have varied results in patients older than 65 years of age. The MDRD equation has been shown to overestimate kidney function in elderly patients, and the CG equation may either overestimate or underestimate renal clearance.^{84,85} Obese patients also present problems when determining renal clearance for the purposes of drug dosing. The MDRD equation has been shown to underestimate renal clearance in obese patients, and the CG equation overestimates renal clearance in obese patients when the total body weight (TBW) is used.⁸⁶ To date no estimating equation has been validated for use in the obese patient population. If an estimating equation is to be used, some data suggest the weight selected should be based on the degree of obesity. A study by Pai and colleagues suggests using TBW in overweight patients (BMI [body mass index] < 30 kg/m²), adjusted body weight (ABW) in obese patients (BMI 30 to <40 kg/m²), and lean body weight (LBW) in morbidly obese patients (BMI ≥ 40 kg/m²).⁸⁷

As a result of the inherent limitations of renal function assessment in critically ill patients, many renal dose adjustment decisions are done with a fair deal of uncertainty. Accordingly, it is essential for the clinician to have a clear understanding of the risks of toxicity associated with excessive dosing as well as the consequences of therapeutic failure associated with underdosing. In some instances aggressive dose reduction may potentially be detrimental. The best example of a situation in which a dose reduction may be delayed is in patients receiving antibiotic therapy. Antibiotics work by a number of different PD parameters as discussed previously, but all require that the concentration at the site of the infection exceed the MIC of the bacteria. Underdosing of antibiotics can have serious implications including selection of resistant organisms and increased morbidity and mortality rates. This is of special concern for patients with severe sepsis and septic shock. Moreover, most antibiotics have relatively wide therapeutic windows; thus, the risk of toxicity is frequently low, even with excessive dosing. In this scenario it may be reasonable to err on the side of higher doses. Therefore, many practitioners will deliver at least one normal dose of an antibiotic before adjusting based on renal function. On the other end of

the spectrum are narrow therapeutic index drugs (i.e., digoxin, lidocaine) that may result in toxicity relatively quickly if changes in renal clearance are not considered. In patients with poor or worsening renal function many of these narrow therapeutic index drugs should be avoided. If use is unavoidable the lowest starting dose should be utilized with frequent toxicity monitoring and assessment of serum concentrations.

DOSING IN RENAL REPLACEMENT THERAPY

Several factors contribute to drug clearance in patients receiving renal replacement therapy (RRT). They can generally be broken down into dialysis, drug, and patient factors. The two methods by which dialysis can remove drugs are diffusion and convection. Diffusion is a passive process during which substances move down a concentration gradient across a dialysis filter. It is the more effective method of drug removal during RRT and is influenced by dialysis filter surface area and composition.⁸⁸ Convection is an active process during which drugs are removed through pressure gradients. Convection removes a smaller percentage of drug and is more dependent on dialysis factors including flow rates and the sieving coefficient of the drug.⁸⁹ However, sieving coefficients are not readily available for most drugs, and therefore the fraction of unbound drug is often used to assess the likelihood of drug clearance.

The three main drug factors that affect clearance are molecular weight, protein binding, and Vd. Drugs with molecular weights exceeding 1000 daltons are not effectively removed by low flux dialysis membranes. However, they may be removed to a larger degree by “high flux” dialysis membranes.⁸⁹ Similar to endogenous clearance mechanisms, clearance by RRT is inversely related to the degree of protein binding and Vd. Because large Vd (>1.5 L/kg) drugs distribute well into tissue, there is limited drug in the serum to be removed, whereas small Vd drugs (<0.7 L/kg) reside primarily in the serum, increasing the likelihood of removal. Other drug factors that may impact clearance are water solubility and plasma clearance. Patient factors include those that affect protein binding (i.e., pH, serum albumin, other drugs, disease states), Vd (volume status, fluid resuscitation), and concomitant organ function.^{89,90}

A number of different methods of RRT may be used in critically ill patients including both intermittent and continuous durations. Because intermittent hemodialysis (IHD) is the most commonly used form of dialysis, drug clearance data are more readily available. As a result, most drug information references will provide dosage recommendations for IHD. Continuous renal replacement therapy (CRRT), on the other hand, provides a number of challenges as there is a lack of pharmacokinetic studies with many drugs. The data that do exist often differ from study to study and are highly dependent on a number of differences including filter composition and surface area, duration of procedure, pre- or postreplacement fluid administration, and flow rates of blood, dialysate, and ultrafiltrate.^{88,90} Therefore, it is important that practitioners evaluate these characteristics for similarities and differences with their patients before applying any dosing recommendation. An in-depth review of the types of RRT and degree of drug removal is beyond the scope of this chapter, but several references are available that provide this information.^{90,91} However, the general

degree of drug removal is as follows: continuous venovenous hemodiafiltration > continuous venovenous hemodialysis > continuous venovenous hemofiltration > slow extended daily dialysis > intermittent hemodialysis.⁹⁰

Once a dosing recommendation has been made in patients receiving CRRT it is important to continue monitoring patients for changes in their dialysis prescription and residual renal function. Dialysis flow rates and ultrafiltration rates often change on a daily basis and can result in alterations in drug clearance. Although CRRT implies that a patient is receiving treatment for 24 hours per day this is frequently not the case. In fact, the reported mean daily stop times for CRRT range from 3 to 8 hours per day owing to a number of reasons including filter clotting, radiologic procedures, catheter exchange, patient mobilization, and surgery.^{92,93} As discussed previously, because it is difficult to estimate drug clearance in patients receiving RRT, careful assessment of the risk-benefit ratio between effectiveness and toxicity is required.

HEPATIC DISEASE

The liver serves as the primary site for drug metabolism, and therefore, drug dosing is an important consideration in any patient with hepatic disease. Hepatic drug clearance (CL_H) is an extremely complex process, dependent on hepatic blood flow (Q_H) and the hepatic extraction ratio (E_H). The hepatic extraction ratio depends on Q_H , intrinsic clearance of unbound drug (CL_{int}), and the fraction of unbound drug in blood (f_u).⁹⁴ The following equations can be used to estimate CL_H :

$$CL_H = Q_H \cdot E_H$$

$$CL_H = Q_H \cdot (f_u \cdot CL_{int}) / (Q_H + f_u \cdot CL_{int})$$

Most data regarding changes in drug clearance are in patients with cirrhosis and therefore do not necessarily apply to acute changes in liver function. Few data are available in patients with acute hepatic dysfunction, making assessments and recommendations in this patient population difficult. Drugs can be categorized as either high or low extraction ratio drugs. Elimination of high extraction ratio drugs is limited by hepatic blood flow and is less sensitive to changes in drug protein binding or enzyme activity (i.e., CL_{int}). After absorption from the GI tract the first stop for all drugs is the liver. High extraction ratio drugs undergo presystemic metabolism commonly referred to as the hepatic first-pass effect. This results in significantly decreased bioavailability and serum drug concentrations. In patients with decreased hepatic blood flow the first-pass effect is decreased, leading to increased serum concentrations and potentially more adverse effects. This effect is most pronounced in drugs that normally have low bioavailability after oral administration.

Low extraction ratio drugs are more sensitive to changes in drug protein binding and enzyme activity (i.e., CL_{int}) and are affected to a lesser degree by changes in blood flow. Plasma protein binding of drugs is decreased in hepatic disease due to a number of reasons including decreased protein production (albumin, AAG) and accumulation of endogenous compounds, which inhibit protein binding. As mentioned previously, this decrease in protein binding can increase free drug exposure for certain drugs, increasing

the risk of adverse effects. Intrinsic hepatic clearance is the ability of the liver to clear unbound drug from the blood. It is highly dependent on the activity of metabolic enzymes and hepatic transporters. These processes may be altered in chronic liver disease, resulting in decreased drug metabolism. The two phases of hepatic metabolism are phase 1 (i.e., hydrolysis, oxidation, reduction) and phase 2 (i.e., acetylation, glucuronidation, sulfation). The cytochrome P-450 family of enzymes is responsible for approximately 75% of drug metabolism and is classified as phase 1 reactions.⁹⁵ Phase 1 metabolism is dependent on molecular oxygen and is thought to be more sensitive to changes that result in decreased oxygen delivery such as to shunting, sinusoidal capillarization, and reduced liver perfusion.^{94,96} Although data demonstrate that enzyme activity is decreased with increasing disease severity, the decreases are variable and nonuniform across the different CYP450 isoenzymes. Although phase 2 metabolism was historically thought to be spared in patients with liver disease, recent data suggest that it is impaired in patients with advanced cirrhosis as well.⁹⁴

ASSESSING HEPATIC FUNCTION

Unfortunately, owing to the complexity of hepatic elimination there are few data to guide drug dosing recommendations in these patients. One of the primary reasons is that a simple method to quantify liver function does not exist. Liver transaminases (i.e., aspartate aminotransferase [AST], alanine aminotransferase [ALT]) are markers of hepatocellular injury and do not reflect synthetic function. Although international normalized ratio (INR) and albumin reflect synthetic capacity they do not adequately capture the complex process of drug metabolism. Although scoring systems have been developed to assess severity of liver disease, no score has been developed for the sole purpose of drug dosing. Although not designed for drug dosing, the Pugh modification of the Child-Turcotte scoring system has been shown to predict changes in drug clearance that occur in hepatic disease.⁹⁷ The scoring system can be found in Table 20.4.⁹⁷ The utility of this score has led to the Food and Drug Administration (FDA) recommendation that it be used to categorize degree of liver impairment in patients enrolled in hepatic PK studies completed during drug development.⁹⁸ There are several limitations to its use in the ICU

Table 20.4 Child-Pugh Classification of Liver Disease

Indicator	1 point	2 points	3 points
Albumin (g/dL)	>3.5	2.8-3.5	<2.8
Prothrombin time (seconds > control)	<4	4-6	>6
Total bilirubin (mg/dL)	<2	2-3	>3
Encephalopathy (grade)	None	1 or 2	3 or 4
Ascites	None	Slight	Moderate
Total score: 5-6 points, mild/group A; 7-9 points, moderate/group B; 10-15 points, severe/group C.			

setting. Unlike equations used in renal disease the Child-Pugh scoring system does not quantify the ability of the liver to metabolize specific drugs. Moreover, it has not been validated in patients with acute liver dysfunction. In addition, it may be influenced by factors in critically ill patients that are not related to liver dysfunction (i.e., depressed albumin from the acute phase response). Despite these limitations, it is still the most useful tool to assess hepatic function at the bedside. Another scoring system, primarily used for prioritizing liver transplantation recipients, is the Model for End-Stage Liver Disease (MELD) score. It has not been adequately studied for drug dosing, and therefore, recommendations should not be made based on the score.

DOSING IN HEPATIC DISEASE

In critically ill patients with chronic hepatic disease it is important that a Child-Pugh score be calculated to assess the degree of liver impairment. Dosing recommendations based on Child-Pugh score are included in the package labeling for many medications and should be referenced when available. When there are no recommendations based on Child-Pugh score, a decision must be made based on clinical judgment. Some general considerations include avoiding drugs metabolized by the CYP450 system in favor of drugs that undergo phase 2 metabolism (i.e., glucuronidation) or renal elimination. If all available choices undergo phase 1 metabolism, then consider the agent with the shortest duration of action. Because the first-pass effect may be reduced in the setting of hepatic dysfunction consider reduced doses of high extraction ratio drug (i.e., drugs which normally have low bioavailability) when using the oral route of administration. Reduce maintenance doses of low hepatic extraction ratio drugs (i.e., drugs with good bioavailability). Although there are few data to support a specific dose reduction with most medications, a reduction of at least 50% is probably warranted in patients with severe disease. A number of valuable references provide more detailed dosing recommendations on a number of medications, and they should be consulted prior to making dosing decisions in these patients.⁹⁹⁻¹⁰²

OBESSE PATIENTS

Approximately 30% of adults in the United States are considered obese.¹⁰³ Available data suggest upward of 25% of all patients admitted to ICUs can be categorized as obese, with 6% to 7% of patients being morbidly obese.^{104,105} These alterations in body weight present potential pharmacokinetic challenges with many drugs that have not been adequately studied in this population.

PHARMACOKINETIC ALTERATIONS IN OBESITY

The two primary pharmacokinetic parameters, Vd and clearance, may be altered in obese patients. The increase in adipose tissue seen in obesity may lead to an increase in Vd for highly lipophilic drugs. This can result in two important changes: a decrease in peak concentration and an increased half-life (see previous discussion of half-life under “General Pharmacokinetic Principles”). The result may be a reduced response to initial doses and an increase in time to reach steady state. The effects of obesity on clearance are less clear. Some studies have shown increased renal and hepatic

blood flow in obese individuals, which should lead to increased clearance. In addition, there is evidence of glomerular hyperfiltration in obese patients.¹⁰⁶ Less clear is how clearance changes with increasing degrees of obesity and how clearance correlates with different body weight parameters. Leading hypotheses related to these questions include the following: (1) Obese individuals exhibit higher absolute clearance than normal weight comparators, (2) clearance does not increase in a linear fashion with TBW, and (3) clearance and LBW are linearly correlated. Unfortunately, not all drugs are affected to the same degree by obesity, and therefore, pharmacokinetic considerations must be made on a drug-drug basis.^{106,107}

DOSING CONSIDERATIONS

The first step in determining a drug dosage for an obese patient is deciding what weight to use. This presents a significant challenge as the ideal weight parameter to use for drug dosing varies among agents. Drugs may be dosed based on ideal body weight (IBW), ABW, TBW, LBW, or body surface area (BSA) (Table 20.5).¹⁰⁸⁻¹¹⁰ TBW may be appropriate for very lipophilic drugs, as Vd increases in a nearly linear fashion with body weight.¹⁰⁶ Drugs with moderate lipophilicity do not distribute completely into adipose tissue and as a result TBW-based recommendations may lead to overdosing of hydrophilic drugs. The ideal weight to use may also vary based on the patient's degree of obesity, which is often assessed using BMI or percentage of ideal body weight (% IBW). Obesity is frequently defined using BMI, with the commonly accepted definition being a value greater than 30 kg/m². However, dosing recommendations based on BMI are frequently unavailable.

Because hydrophilic drugs do not distribute well into adipose tissue other adjustment factors are often used. LBW can be a useful predictor of pharmacokinetic behavior of drugs that are highly water soluble as it accounts for nonfat cell mass and intercellular connective tissue. The term IBW was based on historical data that compared the relative mortality rate of people of different height-weight combinations. It has frequently been used as a surrogate for LBW in

Table 20.5 Equations to Determine Body Size Indicators

Descriptor	Equation
Body mass index (kg/m ²)	TBW/height (m) ²
Body surface area (m ²) (Mosteller formula)	$\sqrt{\frac{(\text{height (cm)} \times \text{TBW})}{3600}}$
Ideal body weight (kg)	Men: 50 kg + 2.3 kg/inches of height over 5 feet Women: 45 kg + 2.3 kg/inches of height over 5 feet
Adjusted body weight (kg)	0.4[TBW – IBW] + IBW
Lean body weight (kg)	Men: [1.1 • TBW] – 120[TBW/height (cm)] ² Women: [1.07 • TBW] – 148[TBW/height (cm)] ²
Percentage of IBW (%)	(TBW/IBW) • 100

IBW, ideal body weight (in kg); TBW, total body weight (in kg).

many pharmacokinetic studies due to ease of use.¹¹¹ Some lipophilic drugs that have an increased Vd in obese patients are dosed based on ABW. Different correction factors have been used to calculate ABW, but the most common factor is 0.4. The equations to calculate these values are listed in Table 20.5.

As with renal and hepatic disease it is imperative to assess the risk-benefit ratio with each drug prior to making any dosing decisions in obese patients. Some drugs have been

studied using different weight parameters and it is always beneficial to know this information prior to deciding on a drug dose. A list of commonly used ICU medications and weight parameters that should be used is provided in Table 20.6.^{107,112-125} Perhaps more concerning is the uncertainty regarding the effect of obesity on the PK/PD of drugs that use fixed doses.

Another consideration should be the safety profile of a particular drug. When using wide therapeutic index drugs

Table 20.6 Optimal Weight Parameter to Use in Dosing Selected Agents in Obese Individuals

Medication	Weight to Use	Special Considerations
Anticoagulants		
Unfractionated heparin (UFH)	TBW	If TBW is used, some practitioners suggest a dose-capping strategy, or the substitution of ABW in morbidly obese patients (BMI >40 kg/m ²) Doses should be adjusted in accordance with TDM
Low-molecular-weight heparin (LMWH)	TBW	TDM in patients >190 kg Prophylaxis: higher-than-normal dose warranted VTE: Dose capping not warranted ACS: Dose capping based on PI
Fondaparinux	TBW	VTE: <50 kg: 5 mg SC daily; 50-100 kg: 7.5 mg SC daily; >100 kg: 10 mg SC daily
Argatroban	TBW	PI dosing up to 140 kg
Lepirudin	TBW	PI recommends dose capping at 110 kg
Bivalirudin	TBW	PI dosing up to 152 kg
Antimicrobials		
Acyclovir	IBW*	Nephrotoxicity, neurotoxicity are dose-limiting side effects
Aminoglycosides	ABW	TDM should be used to adjust dosing
Colistimethate	IBW*	Nephrotoxicity, neurotoxicity are dose-limiting side effects
Daptomycin	TBW	CK should be checked weekly to assess for toxicity
Vancomycin	TBW	TDM should be used to adjust dosing
Antiepileptics		
Phenytoin	LD: ABW MD: IBW	LD should be capped at 2 g; MD should be based on IBW and adjusted by levels
Neuromuscular Blocking Agents		
Succinylcholine	TBW	Dosing based on TBW leads to better conditions for intubation
All others	IBW*	Most data suggest prolonged duration of action with use of TBW to determine dose TOF monitoring and clinical assessment should be used to guide doses in patients requiring continued paralysis
Sedatives		
Benzodiazepines	Bolus: TBW MD: IBW	A less aggressive bolus dose may be warranted in a nonintubated patient in the ICU
Dexmedetomidine	TBW	Has been studied in patients weighing up to 285 kg
Propofol	Bolus: IBW MD: TBW	Data suggest TBW best correlates with Vd and Cl; however, owing to risk of hypotension with bolus dosing and ability to rapidly titrate, it may be appropriate to use IBW for bolus dosing
Thrombolytics		
Alteplase	TBW	AMI: 100 mg standard dose PE: 100 mg standard dose Acute ischemic stroke: 0.9 mg/kg, with total dose capped at 90 mg

*IBW should be used unless the patient's TBW is less than the IBW. In that case, TBW should be used.

ABW, adjusted body weight; ACS, acute coronary syndrome; AMI, acute myocardial infarction; CK, creatine kinase; Cl, clearance; IBW, ideal body weight; LD, loading dose; MD, maintenance dose; PE, pulmonary embolism; PI, package insert; TBW, total body weight; TDM, therapeutic drug monitoring; TOF, train-of-four; Vd, volume of distribution; VTE, venous thromboembolism.

a more aggressive initial approach may be appropriate. This is often the case with β -lactam antibiotics, although a more conservative approach may be warranted with narrow therapeutic index drugs that are dosed based on weight (i.e., phenytoin, sedatives, and digoxin). If therapeutic drug monitoring is available for an agent, it should be used to monitor for achievement of goals, and doses should be based on these valuable data. If therapeutic drug monitoring (TDM) is not available then it may be appropriate to administer small doses of an agent with frequent redosing based on response rather than administering one large dose.

DOSING CONSIDERATIONS WITH SPECIFIC AGENTS IN OBESITY

Antimicrobials

Using the appropriate weight to dose antimicrobial drugs is extremely important, as underdosing may lead to therapeutic failures and overdosing may lead to toxicity (i.e., nephrotoxicity with aminoglycosides or acyclovir). Unfortunately, data are limited for many commonly used antimicrobials. Aminoglycosides are one of the most widely studied antibacterial drugs in obese patients owing to their narrow therapeutic index and widespread availability of serum concentrations. Studies suggest increased aminoglycoside Vd (9-58%) and renal clearance (15-91%) in obese patients.¹²² Their hydrophilic structure and small Vd suggest incomplete adipose distribution, and in fact studies have identified ABW as the optimal weight parameter.¹²² Because both clearance and Vd exhibit substantial variability in obese patients it is extremely important that therapeutic drug monitoring be used to optimize aminoglycoside dosing in this cohort.

As with aminoglycosides, numerous studies in the literature evaluate vancomycin kinetics in obesity. These studies demonstrate variable changes in Vd and increased clearance in obesity.¹²² Current vancomycin guidelines recommend that patients should be dosed on TBW with adjustments in dosing regimen based on therapeutic drug monitoring.³⁷ However, this is somewhat controversial as patients weighing more than 100 kg would receive loading doses exceeding 2 g. These are substantially larger than what has been used in the past, and in light of the uncertainty regarding nephrotoxicity with increasing trough level, some clinicians may not be comfortable with this aggressive approach to loading doses. However, with the AUC:MIC ratio being the pharmacodynamic parameter that best correlates with clinical efficacy, weight-based dosing with TDM should be used to optimize therapy.

Other available antimicrobials that are dosed based on weight include acyclovir, colistimethate sodium, daptomycin, and sulfamethoxazole/trimethoprim (SMX/TMP). Acyclovir is a relatively hydrophilic drug, and therefore IBW should be used for dosing in obese patients.^{112,126} Nephrotoxicity has been reported in obese patients who receive acyclovir dosed on TBW.¹²⁷ Data regarding the optimal dosing weight for colistimethate sodium are limited. However, one recent study suggests using IBW unless the patient's TBW is less than IBW.¹²⁸ Currently available data with daptomycin suggest dosing based on TBW.¹²⁹ However, patients must be monitored for elevations in creatine kinase

(CK) on a weekly basis as rhabdomyolysis would be the primary adverse effect of concern. There are insufficient data to make a recommendation on dosing of the lipophilic antibiotic SMX/TMP in obese patients. If available and high-dose SMX/TMP therapy is necessary, therapeutic drug monitoring should be used to guide dosing.

Several antibiotic classes are not normally dosed based on weight, including penicillins, cephalosporins, carbapenems, and fluoroquinolones. There are relatively few pharmacodynamic data in obese patients for these classes. However, these drugs are generally well tolerated and therefore it is probably reasonable to use aggressive dosing strategies in these patients (i.e., maximal studied doses or less aggressive adjustment for renal dysfunction). This approach may not be prudent in patients at increased risk of particular adverse effects such as seizures with imipenem or rate-corrected QT interval (QTc) prolongation with fluoroquinolones.

Sedatives

Benzodiazepines, dexmedetomidine, and propofol are the most commonly used sedatives in the ICU. The benzodiazepines are highly lipophilic compounds that have significantly increased Vd and clearance in obese patients.¹³⁰ Because they demonstrate an increased Vd the use of TBW has been suggested for bolus doses of benzodiazepines. However, the risk of respiratory depression in patients without an advanced airway is an important consideration. Because the parenteral benzodiazepines all have relatively rapid onset the use of smaller doses based on IBW repeated every 5 to 15 minutes is a reasonable approach in patients without an advanced airway. In one study midazolam half-life was increased nearly threefold in obese patients.¹¹⁹ This effect increases the risk of accumulation, oversedation, and delirium in obese patients, especially with continuous infusions. When benzodiazepines must be used, intermittent doses based on IBW are preferred.

Although propofol is a highly lipophilic compound, available data do not demonstrate changes in Vd or clearance in obese patients. This information would suggest that TBW should be used for maintenance doses in this patient population.^{124,131} However, propofol is associated with several significant adverse effects including hypotension with bolus dosing and the life-threatening propofol-related infusion syndrome (PRIS) with high doses or extended durations of infusion. Owing to the hemodynamic complications associated with propofol an initial bolus based on IBW followed by additional small doses might be reasonable. Because it is a short half-life drug it can be rapidly titrated to effect. High doses and the risk of PRIS represent a more complicated therapeutic dilemma. One of the recognized risk factors is a dose of propofol exceeding 83 $\mu\text{g/kg/minute}$.¹³² It is not known how dosing based on TBW vs. IBW would affect the development of PRIS. Therefore, these patients should be closely monitored for symptoms of PRIS including metabolic acidosis, lactate, hyperkalemia, rhabdomyolysis, an elevated CK, or cardiac failure. If these symptoms develop, they should have propofol stopped immediately.¹³² Pharmacokinetic data for dexmedetomidine in critically ill patients is not readily available. However, dexmedetomidine has been studied in patients up to 285 kg using TBW and the manufacturer provides dosing recommendations based on TBW for patients weighing up to 185 kg.¹²⁵ If TBW is used,

then it is important that the dose be titrated to effect with monitoring for hypotension and bradycardia.

Anticoagulants

Anticoagulant dosing in obesity presents challenges because overdosing may result in bleeding complications and underdosing can result in worsening of thrombosis. Weight has been reported to be the single best predictor of unfractionated heparin (UFH) requirements with numerous weight-based nomograms being published.¹³³ TBW is frequently used for UFH dosing in nonobese and non-morbidly obese patients. However, the exact weight parameter that should be used in morbid obesity (BMI > 40 kg/m²) is unclear. When TBW is used in morbid obesity there is a higher rate of supratherapeutic activated partial thromboplastin time (aPTT).^{134,135} Despite the potential for higher than anticipated aPTTs several studies reported no difference in major bleeding events or rates of primary event recurrence when UFH was dosed on TBW.^{136,137} Owing to the lack of prospective data in this patient population some practitioners recommend dosing on an ABW or a dose-capping strategy if TBW is used.^{134,138} This decision may be influenced by the indication and risk for bleeding with practitioners using a more aggressive approach in the treatment of VTE and a less aggressive dosing approach for atrial fibrillation or acute coronary syndrome (ACS). Regardless of what weight is used for the bolus dose, the subsequent infusion should be adjusted based on therapeutic drug monitoring.

Unlike UFH there has been significantly more research on the ideal weight parameter for low-molecular-weight heparins (LMWHs) with TBW being identified as the best predictor of LMWH requirements.¹²¹ Pharmacodynamic data for LMWHs are available in patients weighing up to 190 kg.¹³⁹ Because of the limited data in patients more than 190 kg some practitioners recommend a dose-capping strategy at this weight. Although a dose-capping strategy may seem prudent, there are no data to suggest this will limit bleeding risk while still achieving the therapeutic goal. With this in mind a more prudent approach is to use TBW for VTE treatment doses in patients weighing more than 190 kg combined with TDM to avoid excessive exposure. If TDM is used, an anti-factor Xa level should be checked 4 hours after the third dose of a LMWH. Because VTE doses are not weight based, current guidelines recommend using an increased fixed dose of LMWH in obese patients.¹¹⁸ However, specific recommendations are not made regarding dose adjustments largely because of variability in the available data. Several available reviews provide a more detailed discussion of the available anticoagulants for prophylaxis, VTE, and ACS in the obese patient population.^{121,123,140}

ELDERLY PATIENTS

Current estimates from the administration on aging predict that by 2050 approximately 20% of the U.S. population will be older than 65.¹⁴¹ As a result elderly patients will make up a larger percentage of ICU admissions. These patients frequently have multiple chronic diseases and are at increased risk for polypharmacy. Unfortunately, prior to 1990 drug companies were not required to study drugs in elderly patients. This leads to a lack of dosing recommendations that are specific to the elderly patient population.

As individuals age a number of physiologic changes occur that lead to significant pharmacokinetic alterations. Drug absorption may be decreased as a result of changes in gastric pH, gastric emptying, splanchnic blood flow, and GI motility. Half-life and Vd may be increased for lipophilic drugs as a result of increases in body fat and decreases in lean body mass. Hydrophilic drugs will have increased serum concentrations because of decreases in total body water. The free fraction of highly protein bound drugs is increased as a result of decreases in serum protein production. Decreases in hepatic blood flow and hepatic mass may result in decreased hepatic first-pass effect and potentially decreased phase 1 metabolism. Age-related decreases in renal blood flow and GFR may result in impaired renal drug elimination.¹⁴² Unfortunately, these changes vary among patients, making drug dosing especially challenging.

In an effort to minimize polypharmacy and adverse drug effects several criteria have been developed to screen medication therapy in elderly patients. The most commonly cited are the Beers' criteria, originally developed in 1991 and updated in 2012.¹⁴³ The most recent version includes 53 medications or medication classes divided into 3 categories. A newer set of recommendations that are gaining popularity are the STOPP (Screening Tool of Older Persons' potentially inappropriate Prescriptions) criteria. They consist of 64 medications or medication classes divided into 10 categories. Both criteria have been validated and at least one should be used in the evaluation of the appropriateness of medications in elderly patients. In addition to the use of screening criteria drug therapy should be started at a low dose and carefully titrated until the lowest effective dose is achieved.

PREGNANCY

Pregnancy is a dynamic state with physiologic changes occurring throughout gestation. These changes include alterations in cardiovascular, pulmonary, GI, renal, and hepatic function that may result in clinically significant changes in drug PK.¹⁴⁴ Pregnant patients are frequently excluded from PK trials, limiting data that describe PK/PD and fetal adverse effect profiles for many drugs commonly used in critically ill pregnant patients. An in-depth discussion of all drug classes in pregnancy is beyond the scope of this chapter. There are several good review articles in the literature for specific drugs or disease states that should be reviewed prior to using the agents in pregnancy.^{145,146}

PREGNANCY PHARMACOKINETIC CHANGES

Pregnancy results in multiple physiologic changes that affect absorption, distribution, metabolism, and elimination of various drugs. Absorption may be decreased due to a reduction in GI motility and an increased gastric pH. However, these changes are minimal and therefore are unlikely to significantly alter outcomes. Distribution is potentially increased due to changes in volume (up to 50% increase in blood volume) and decreases in protein binding (up to 30% decreases in albumin). These changes may lead to either lower or higher concentrations of free drug in the serum depending on the properties of the agent administered. Pregnancy increases hepatic blood flow and has variable effects on CYP enzymes. Available data suggest an

increased activity of CYP26, CYP2C9, CYP2A6, and CYP3A3 and a decrease in the activity of CYP1A2 and CYP2C19. Renal elimination increases throughout gestation with an 80% increase in renal plasma flow during the second trimester, leading to a 50% increase in GFR. Consequently, pregnant women will often require higher doses of drugs with renal elimination; however, this requirement will change throughout pregnancy.¹⁴⁷

The more important drug-related concern in pregnant women is the risk for the medications to affect fetal development. The system commonly used to evaluate teratogen risk in the United States is the FDA category system. Pregnancy categories include A (controlled clinical studies in humans showing safety), B (animal studies show no risk AND human data lacking), C (animal studies show risk AND human data lacking), D (human data show risk, benefit > risk), and X (animal or human data show significant risk, risk > benefit). In 2008 the FDA proposed major revisions to the drug labeling for pregnancy and lactation. The proposed changes are designed to provide better information when making prescribing decisions. Once the changes are approved they will replace the old pregnancy categories. However, at the time of this writing they are still under review.

In a best-case scenario we would use only category A drugs in critically ill pregnant women. However, because pregnant women are a protected research population they are frequently excluded from clinical trials; therefore, few drugs are listed as category A for pregnancy. Many agents that are category B or C can often be used safely in pregnancy. If available, category A, B, or C drugs should be used. However, if the indicated drug is category D and there are no alternatives, a careful risk-benefit assessment must be undertaken. Many antiepileptic drugs (AEDs) are pregnancy category D, making acute seizure management challenging in pregnancy. Levetiracetam is a pregnancy category C drug and is preferred over other agents. Out of the many AEDs that are category D drugs, valproic acid is believed to have the highest fetal risk and therefore should be avoided.¹⁴⁸ Category X drugs are contraindicated in pregnancy. [Table 20.7](#) lists some commonly used ICU drugs and their pregnancy categories.¹⁴⁹⁻¹⁵³

BURN INJURY

Two phases of burn injury have significant effects on PK and PD. The first 48 hours following injury are characterized by hypovolemia, edema, hypoalbuminemia, and decreases in GFR. The second phase occurs beyond 48 hours and is a hyperdynamic state. During this hyperdynamic phase patients will have increased renal and hepatic blood flow, altered serum protein production, and insensible drug losses through exudate leakage resulting in altered binding, distribution, and clearance.¹⁵⁴

The pharmacokinetic changes seen with burn injury vary from patient to patient, making drug dosing recommendations difficult. A 2008 review article discusses the available pharmacokinetic data.¹⁵⁴ As with other disease states, therapeutic drug monitoring should be used if available to determine drug doses. Because significant changes in serum proteins are common, the use of levels that detect free drug concentrations are preferred. If free levels are not available, clinicians must be aware that a total level in the therapeutic

range does not necessarily reflect an appropriate drug dose. In these situations physical and laboratory assessment to evaluate therapeutic efficacy and adverse effects is warranted. If TDM is not available and the agent is a wide therapeutic index drug, then using maximal drug dosing is acceptable to ensure therapeutic effect.

HYPOTHERMIA

The process of cooling patients to mild hypothermia (32–34°C) has been studied for a number of different conditions including traumatic brain injury, spinal cord injury, stroke, cardiac surgery, and cardiac arrest.¹⁵⁵ It is most frequently used after cardiac arrest and is currently a recommended treatment in comatose adult patients following out-of-hospital ventricular fibrillation cardiac arrest. In addition, the guidelines from the American Heart Association suggest it may be beneficial for other cardiac arrest patients including in-patients and those with nonshockable rhythms.¹⁵⁶ With the increasing prevalence of hypothermia for cardiac arrest and the potential for use in other indications it is important to understand the impact hypothermia has on drug PK.

Hypothermia results in multiple physiologic changes that may impact the kinetics and dynamics of certain agents. Available literature report varied effects of hypothermia on drug absorption, distribution, drug target affinity, and time to onset.¹⁵⁷ However, hypothermia has been repeatedly shown to decrease drug clearance. This is especially true for drugs that undergo hepatic metabolism via the CYP450 system. Midazolam is one of the most studied drugs in hypothermia because of its frequent use as a sedative and metabolism by CYP3A4 and CYP3A5. One study in traumatic brain-injured patients cooled to less than 35°C demonstrated a fivefold increase in midazolam serum concentrations and a 100-fold decrease in clearance compared to a group of normothermic patients.¹⁵⁸ Data from healthy volunteers predicted an 11% decrease in midazolam clearance for every 1°C decrease in temperature below 36.5°C.¹⁵⁹ This is an important consideration, as it may result in a prolonged duration of pharmacologic effect, even after rewarming. Similar results have been reported for other drugs metabolized by the CYP450 family of enzymes.¹⁶⁰

Although hypothermia has been shown to alter the clearance of drugs metabolized by the CYP450 family of enzymes, there are fewer data on the impact of hypothermia on toxicity. Pending further research it is important for ICU practitioners to recognize drugs that are metabolized by the liver and to monitor drug levels when possible and other markers of drug efficacy (i.e., sedation scores).

PHARMACOGENETICS

Pharmacogenetics is the study of genetic polymorphisms between patients, and pharmacogenomics takes a genome-wide approach in the study of drug response polymorphisms. The first reports of genetic polymorphisms affecting drug response were published in the 1950s. One of these early reports involved prolonged apnea after succinylcholine administration in patients with a variant of the enzyme responsible for succinylcholine metabolism.¹⁶¹ It has become

Table 20.7 Medications Commonly Used in the Intensive Care Unit (ICU)* and Associated Pregnancy Risk

Drug Class	Pregnancy Risk Category		
	Category A, B, or C [†]	Category D [‡]	Category X [§]
Anticoagulants	<i>Preferred:</i> LMWH <i>Second line:</i> UFH <i>Only for use in patients with HIT:</i> Fondaparinux Argatroban Bivalirudin Lepirudin		Warfarin
Antiepileptics— IV drugs only	Lacosamide Levetiracetam	Phenobarbital Phenytoin Valproic acid Nitroprusside Enalaprilat	
Antihypertensives— IV drugs only	<i>Preferred:</i> Labetalol Hydralazine <i>Second line:</i> Nicardipine		
Antimicrobials	<i>First line:</i> Amphotericin B Carbapenems Cephalosporins Penicillins <i>Second line:</i> Fluoroquinolones Vancomycin	Aminoglycosides Amikacin Gentamicin Tobramycin Fluconazole Metronidazole Nitrofurantoin Sulfamethoxazole-trimethoprim Voriconazole	
Sedatives	Propofol Dexmedetomidine	Lorazepam Midazolam	
Miscellaneous	Furosemide	Amiodarone Spironolactone Nonsteroidal anti-inflammatory drugs	HMG-CoA reductase inhibitors Spironolactone

*This list is not all-inclusive. The risk-benefit ratio must be weighed before any drug is used in pregnant patients.

[†]Human data show no risk or low risk or are lacking.

[‡]Human data show risk, but risk may outweigh benefit.

[§]Contraindicated.

^{||}Antimicrobials should not be withheld because of pregnancy, especially if alternatives are associated with worse infection-related outcomes.

HIT, heparin-induced thrombocytopenia; HMG-CoA, β -hydroxy- β -methylglutaryl-coenzyme A; IV, intravenous; LMWH, low-molecular-weight heparin; UFH, unfractionated heparin.

an area of increasing interest with variants identified that cause alterations in metabolism, transport, and drug interactions.¹⁶² Unfortunately, to date few studies have assessed the impact of polymorphisms on agents commonly used in the ICU. A 2010 review discusses some of the genetic polymorphisms that are most likely to impact drug therapy in the ICU.¹⁶³ As this area of research continues to grow and more data become available it is likely that pharmacogenetics will have a significant impact on care of the critically ill patient.

Genetic variations in metabolism are some of the best understood genetic polymorphisms. Variations have been described for both phase 1 and phase 2 reactions. These variations may result in patients becoming extensive or poor metabolizers and may result in increased toxicity or decreased efficacy. The majority of research has focused on the cytochrome P-450 family because it is responsible for

approximately 75% of all drug metabolism. Within the CYP family most research has focused on 2D6, 2C19, and 2C9. The most studied of these enzymes is 2D6, with variants being associated with increased serum concentrations of carvedilol, metoprolol, and flecainide although decreased response is observed with codeine and tramadol. Variants in CYP2C9 are associated with increased dose response to warfarin and variants in CYP2C19 are associated with decreased efficacy of clopidogrel and the proton pump inhibitors.¹⁶³ Other metabolizing enzymes that have variant alleles include *N*-acetyltransferase 2 and thiopurine *S*-methyltransferase. Slow acetylators of hydralazine, procainamide, and sulfamethoxazole are at an increased risk of immune-related toxic conditions such as systemic lupus erythematosus. On the other hand, slow acetylators of isoniazid are at increased risk of neurotoxicity, and rapid acetylators have an increased risk of hepatitis.

Even though a number of commonly used ICU drugs are metabolized by these enzymes, prescribing based on pharmacogenetics and phenotyping is still uncommon. The reasons are multifactorial and are in part due to the lack of data showing improved outcomes and the expenses associated with the tests. In fact, guideline statements recommended against routine pharmacogenetic screening prior to the use of clopidogrel or warfarin.^{164,165} Until further data are available these recommendations are unlikely to change. Based on current studies there isn't much of a role for

routine pharmacogenetic testing in critically ill patients. However, as more data become available it may become a standard of care in the ICU.

PRINCIPLES OF THERAPEUTIC DRUG MONITORING

As discussed previously, most of the currently available drugs have few clinical trial data in critically ill patients. This

Table 20.8 Therapeutic Monitoring for Commonly Used Drugs*

Drug	Type/Timing of Level	Therapeutic Concentration		Notes
Antiepileptics				
Phenobarbital	<i>Trough:</i> 0-30 minutes before dose	20-40 µg/mL		Phenobarbital is a long-half-life drug (36-125 hours), so a significant amount of time will be required to achieve steady state after a dosage adjustment
Phenytoin	<i>Trough:</i> 30 minutes before dose <i>Peak:</i> 1 hour after loading dose in setting of status epilepticus	Free level: 1-2 µg/mL Total level: 10-20 µg/mL		Free levels should be checked in patients with decreased albumin or renal disease or in the presence of displacers (e.g., valproic acid)
Valproic acid	<i>Trough:</i> 30 minutes before dose	50-100 µg/mL		Some patients may require levels from 100 to 150 µg/mL to achieve efficacy but are at increased risk for adverse effects
Antimicrobials				
Aminoglycosides Traditional dosing	<i>Peak:</i> 30 minutes after dose <i>Trough:</i> 30 minutes before dose	Gentamicin/ tobramycin peak (µg/mL) 5-10	Gentamicin/ tobramycin trough (µg/mL) 1-2	Peak goals vary depending on indication/source of infection Amikacin goals are 3× gentamicin/ tobramycin goals
High-dose extended-interval dosing	<i>Two random levels:</i> between 6 and 14 hours after dose	Gentamicin/ tobramycin peak (µg/mL) 15-25	Gentamicin/ tobramycin trough (mg/L) <1	Peak goals for doses of 5-7 mg/kg/day of gentamicin/tobramycin Amikacin dose and goals are 3× the gentamicin/ tobramycin goals
Vancomycin	<i>Trough:</i> 30-60 minutes before dose	10-20 µg/mL		Trough goal dependent on severity and location of infection Some data suggest a goal AUC/MIC of ≥400
Cardiac				
Digoxin	<i>Random level:</i> at least 6 hours after dose	Heart failure: 0.5-0.8 ng/mL Rate control: <2 ng/mL		Rates of adverse effects increased significantly above 2 ng/mL For rate control, the lowest effective dose that achieves effect should be used
Immunosuppressants				
Cyclosporine	<i>Trough:</i> 12 hours after dose	100-400 ng/mL		Goal dependent on indication and time since initiation
Tacrolimus	<i>Trough:</i> 12 hours after dose	5-20 ng/mL		Goal dependent on indication and time since initiation

*If patient presents with symptoms of drug failure or toxicity, it may be reasonable to check serum concentration for all drugs before steady state is attained.

AUC, area under the curve; MIC, minimum inhibitory concentration.

lack of information leads to the extrapolation of data from non-critically ill patients, which may lead to therapeutic failure or toxicity. In this situation TDM can play an important role. Simply put, TDM is the development of a drug-dosing protocol based on static serum concentrations. The goal of this approach is to maximize therapeutic efficacy while minimizing the potential adverse effects associated with supratherapeutic concentrations. Unfortunately, TDM is not appropriate for all medications, and several factors must be assessed before TDM can be performed in any medication.

Several factors make a medication appropriate for TDM: (1) An assay is available that is accurate, specific, and can be conducted in a timely manner, (2) adequate pharmacokinetic data exist for the drug and they show significant interindividual variability, (3) there is a narrow range between therapeutic and toxic effects and these effects are proportional to the serum concentrations, (4) the therapeutic and toxic ranges are clearly defined, and (5) a constant pharmacologic effect is seen over time.¹⁶⁶

After the decision is made to check a serum concentration, several factors must be evaluated as they are likely to influence the interpretation of the data. These factors include but are not limited to the time, duration, dose, and route of drug administration; the time the samples were drawn in relation to the previous and subsequent doses; whether the assay measures free or total (bound plus unbound) drug; patients' concomitant disease states; and the response to therapy and presence of adverse effects. Failure to consider these variables may lead to misinterpretation of the data. Although the data obtained through TDM can be extremely helpful, the practitioner must not forget to compare the results to the clinical presentation of the patient. This is important because not all patients are the same and what is therapeutic in one patient may be toxic in another even if the serum concentrations are the same. This variability makes assessing the patient's response to therapy even more important.

In general we reserve TDM for drugs that are associated with an increased risk for toxicity due to a narrow therapeutic index. The optimal time to monitor serum drug concentrations is highly dependent upon the drug being used and the patient's clinical presentation. However, after any dosage change a drug should reach steady state (5-7 drug half-lives) before a serum concentration is checked. There are some exceptions to this rule, for example, after a loading dose of phenytoin or valproic acid in a patient who does not appear to respond or after the first dose of an aminoglycoside if a high-dose extended-dosing nomogram is being used. The other situation when serum concentrations may be checked at different intervals is in a patient who has changing organ function. Table 20.8 lists some drugs that have clearly defined therapeutic concentrations and for which TDM is commonly utilized.⁵² Several medications are not included in this table because serum drug concentrations are not routinely monitored but markers of their efficacy are monitored (i.e., heparin, LMWHs, direct thrombin inhibitors). In addition, there are a number of other medications for which TDM may become more prevalent in the future but TDM is not currently the standard of care. Some potential

examples include β -lactam antibiotics, levetiracetam, and mycophenolate mofetil.

CONCLUSION

In order to maximize the efficacy and minimize toxicities associated with medications it is important for practitioners to understand the basic principles of PK and PD. This knowledge becomes even more important in critically ill patients who undergo a number of physiologic changes and have a number of disease states that result in altered drug responses. All medication regimens in critically ill patients should be individualized based on knowledge of a drug's kinetics and dynamics along with an understanding of the impact the patient's comorbid conditions will have on these parameters. In addition, therapeutic drug monitoring should be utilized if available, particularly with narrow therapeutic index drugs. Through the vigilant use of this knowledge practitioners can maximize therapeutic outcomes in their patients while minimizing toxicity.

KEY POINTS

- Most drug-dosing recommendations are based on studies in healthy volunteers and often do not account for the pharmacokinetic and pharmacodynamic alterations seen in critically ill patients.
- Alterations in drug absorption, distribution, metabolism, and clearance are common in critically ill patients, and failure to modify drug dosages based on these changes may result in increased drug toxicity or treatment failure.
- The pharmacodynamic parameter that determines efficacy varies among drug classes as demonstrated by the different targets to maximize bacterial kill among aminoglycosides (concentration dependent, peak:MIC ratio), β -lactams (time dependent, $T > MIC$), and vancomycin (time and concentration dependent, AUC/MIC).
- Physiologic changes seen with critical illness may alter the rate and extent of medication absorption from the GI tract, making IV administration the preferred route in patients with hemodynamic instability.
- Commonly encountered factors in critically ill patients that impact drug PK and PD include renal disease, hepatic disease, obesity, advanced age, pregnancy, thermal injury, and hypothermia.
- Current data do not support routine pharmacogenetic testing for critically ill patients; however, as more data become available it may become a standard of care for some medications.
- When available, patient-specific PK based on appropriately timed serum concentrations (i.e., therapeutic drug monitoring) should be used to minimize toxicity and maximize the efficacy of drug therapy.

CONCLUSION

INTRODUCTION

The syndrome of shock in humans is often the final pathway through which a variety of pathologic processes lead to cardiovascular failure and death. As such, it is perhaps the most common and important problem with which critical care physicians contend. The importance of shock as a medical problem can be appreciated by the prominence of its three dominant forms. Cardiogenic shock related to pump failure is a major component of the mortality associated with cardiovascular disease, the leading cause of death in the United States with almost 800,000 deaths annually.¹ Similarly, hypovolemic shock remains a major contributor to early mortality from trauma, the most common cause of death in those between the ages of 1 and 45 (approximately 200,000 cases annually).^{1,2} Finally, despite improving medical and surgical therapy, overall mortality coded as septicemia has increased from the 13th to the 11th most frequent cause of death in the United States.^{1,3} Most current estimates suggest that there are more than 100,000 cases of septic shock annually in the United States alone.^{4,5} In addition, all forms of shock increase the probability of other major comorbidities such as serious infection, acute respiratory distress syndrome (ARDS), and multiple organ dysfunction syndrome (MODS).

This chapter provides an overview of circulatory shock with an emphasis on the common elements and important differences in the pathophysiology and pathogenesis of the various forms of the syndrome. This focus on common elements of different forms of shock will continue through sections on systemic shock hemodynamics, microvascular dysfunction, mechanisms of cellular injury, oxygen supply dependency, compensatory responses, diagnostic approach/evaluation, and management/therapy.

HISTORY

Despite recognition of a posttraumatic syndrome by Greek physicians such as Hippocrates and Galen, the origin of the term *shock* is generally credited to the French surgeon Henri Francois Le Dran who, in his 1737 “A Treatise of Reflections Drawn from Experience with Gunshot Wounds,” coined the term *choc* to indicate a severe impact or jolt.⁶ An inappropriate translation by the English physician Clarke, in 1743, led to the introduction of the word *shock* to the English language to indicate the sudden deterioration of a patient’s condition with major trauma.⁶ It was Edwin A. Moses,⁷ however, who began to popularize the term, using it in his 1867 “A Practical Treatise on Shock after Operations and Injuries.” He defined it as “a peculiar effect on the animal system, produced by violent injuries from any cause, or from violent mental emotions.” Prior to this definition, the rarely used term *shock* referred in a nonspecific sense to the immediate and devastating effects of trauma, not a specific

 Additional online-only material indicated by icon.

posttrauma syndrome. Although not entirely accurate by today's standards, his definition was one of the first to separate the syndrome involving the body's response to massive trauma from the immediate, direct manifestations of trauma itself.

By the late 1800s, two theories of traumatic shock physiology dominated. The first, based on observations by Bernard, Charcot, Goltz, and others, was proposed by Fischer in 1870.⁸⁻¹⁰ He suggested that traumatic shock was caused by generalized "vasomotor paralysis" resulting in splanchnic blood pooling. The corollary was that total circulating blood volume is preserved in shock. The second dominant theory, articulated by Mapother in 1879, suggested that decreased cardiac output in traumatic shock is caused by intravascular volume loss due to extrusion of plasma through the vessel wall from the intravascular space to the interstitium.¹¹ He proposed that this was a consequence of the failure of "vasodilator nerves" in traumatic shock and subsequent generalized arteriolar vasoconstriction. With the 1899 publication of "An Experimental Research into Surgical Shock" (perhaps the first experimental studies of shock), George W. Crile provided scientific data supporting a variation of the vasomotor paralysis theory.¹² After documenting the importance of decreased central venous pressure and venous return in experimental shock due to hemorrhage and demonstrating the potential for intravascular volume replacement as therapy, he proposed that traumatic shock was caused by exhaustion of the overstimulated "vasomotor center" and subsequent generalized relaxation of large vessels (veins) leading to decreased ventricular filling and cardiac output.

Further advances in shock research were substantially driven by military concerns. During World War I, Walter B. Cannon and other physiologists/physicians studied the early clinical response to battlefield trauma. Their work eventually led to the publication of the classic monograph "Traumatic Shock" in 1923.¹³ Cannon and his colleagues were the first to relate trauma-associated hypotension in a large group of patients to a fall in blood volume, loss of bicarbonate, and accumulation of organic acids. Others, using dye dilution techniques, demonstrated that severity of shock was directly related to the decrease in intravascular volume.¹⁴ Clinical data from war casualties also suggested the importance of reduced blood flow (independent of blood pressure) in shock.¹⁵ The observation that blood in the capillaries of victims of massive trauma was hemoconcentrated compared to venous blood would lead to the practice of resuscitating trauma patients with dried pooled plasma rather than whole blood in the early part of World War II.¹⁶

Although work originating from the battlefields of World War I clearly linked traumatic shock associated with substantial, obvious bleeding to a loss of circulating blood volume, the origin of traumatic shock in the absence of defined hemorrhage was unclear. The accepted explanation for this phenomenon remained a variation of the vasomotor paralysis theory of shock. It was postulated that nonhemorrhagic, posttraumatic shock ("wound shock") was caused by the liberation of "wound toxins" (histamine or other substances), which resulted in *neurogenic* vasodilation and peripheral blood pooling. However, after the war, Blalock and others demonstrated in animal models that nonhemorrhagic traumatic shock was due to the loss of blood and

fluids into injured tissue rather than circulating toxins resulting in stasis of blood within the circulation.¹⁷

Additional advances occurred during World War II. Using injured subjects from the European front, Henry Beecher confirmed that hemorrhage and fluid loss leading to metabolic acidosis was a major cause of shock.¹⁸ In the first use of indicator dye techniques in humans for studying blood flow, Cournand and Richard, in 1943, demonstrated that cardiac output was typically reduced in shock.¹⁹ They also reinforced Blalock's findings regarding nonhemorrhagic "wound shock" in trauma patients by demonstrating that circulating blood volume was reduced in such patients through loss of fluid into damaged tissues. The importance of maintaining intravascular volume in traumatic and hemorrhagic shock was supported by the well-known cardiovascular physiologist, Carl J. Wiggers, who published a landmark series of studies²⁰ in the 1940s using a standardized animal model, which showed that prolonged hypovolemic shock resulted in a resuscitation-resistant state that he termed *irreversible shock*. He defined it as a condition resulting from "a depression of many functions but in which reduction of the effective circulating blood volume is of basic importance and in which impairment of the circulation steadily progresses until it eventuates in a state of irreversible circulatory failure." Aggressive fluid support became the standard of resuscitation for trauma and shock.

Subsequently, the Korean War fueled the research that demonstrated the relationship of acute tubular necrosis (ATN) and acute renal failure (ARF) to circulatory shock.²¹ In addition, studies of battlefield casualties clearly demonstrated the relationship between early resuscitation and survival.²¹ During the Vietnamese conflict, with the widespread use of ventilator technology, the dominant research concern became postshock infection and "shock lung" (ARDS), a concern that has evolved to the present interest in shock-related MODS.

DEFINITIONS AND CATEGORIZATION OF SHOCK

The definition of shock has evolved in parallel with our understanding of the phenomenon. As noted, until the late 1800s, the term *shock* was used to indicate the immediate response to massive trauma, without regard to a specific posttrauma syndrome. The definition consisted of descriptions of its obvious clinical signs. In 1895, John Collins Warren²² referred to shock as "a momentary pause in the act of death," which was characterized by an "imperceptible" or "weak, threadlike" peripheral pulse and a "cold, clammy sweat."

Subsequently, with the introduction of noninvasive blood pressure monitoring devices, most clinical definitions of shock added the requirement for arterial hypotension. In 1930, Blalock⁸ included arterial hypotension as one of the required manifestations of shock when he defined it as "peripheral circulatory failure resulting from a discrepancy in the size of the vascular bed and the volume of the intravascular fluid." Simeone,²³ as recently as 1964, suggested that shock exists when "the cardiac output is insufficient to fill the arterial tree with blood under sufficient pressure to provide organs and tissues with adequate blood flow."

Current technology, which allows for the assessment of perfusion independent of arterial pressure, has shown that hypotension does not define shock. The emphasis in defining shock is now on tissue perfusion in relation to cellular function. According to Fink,²⁴ shock is “a syndrome precipitated by a systemic derangement of perfusion leading to widespread cellular hypoxia and vital organ dysfunction.” Cerra²⁵ has emphasized supply/demand mismatch in his definition: “a disordered response of organisms to an inappropriate balance of substrate supply and demand at a cellular level.”

The appropriate definition of shock varies with the context of its use. For paramedical personnel, a definition that incorporates the typical clinical signs of shock (arterial hypotension, tachypnea, tachycardia, altered mental status, and decreased urine output) may suffice. For the physiologist, shock may be defined by specific hemodynamic criteria involving alterations of ventricular filling pressures, venous pressures, arterial pressures, cardiac output, and systemic vascular resistance. Similarly, in the appropriate context, shock could also be defined by alterations of biochemical/bioenergetic pathways or intracellular gene expression. For the physician, however, we find the most appropriate definition to be “the state in which profound and widespread reduction of effective tissue perfusion leads first to reversible, and then, if prolonged, to irreversible cellular injury.”

Effective tissue perfusion, as opposed to tissue perfusion per se, is an important issue. Effective tissue perfusion may be reduced by either a global reduction of systemic perfusion (cardiac output) or by increased ineffective tissue perfusion due to a maldistribution of blood flow or a defect of substrate utilization at the subcellular level (Box 21.1).

CLASSIFICATION

Although hypovolemic shock associated with trauma was the first form of shock to be recognized and studied, by the early 1900s it became broadly recognized that other clinical conditions could result in a similar constellation of signs and symptoms. Sepsis as a distinct cause of shock was initially proposed by Laennec (1831) and subsequently supported by Boise (1897).^{26,27} In 1934, Fishberg and colleagues introduced the concept of primary cardiogenic shock due to myocardial infarction.²⁸ Later the same year, Blalock developed the precursor of the most commonly used classification systems of the present.²⁹ He subdivided shock into four etiologic categories: hematogenic or oligemic (hypovolemic), cardiogenic, neurogenic (e.g., shock after spinal injury), and vasogenic (primarily septic shock). Shubin and Weil, in 1967, proposed the additional etiologic categories of hypersensitivity (i.e., anaphylactic), bacteremic (i.e., septic), obstructive, and endocrinologic shock.³⁰ However, as the hemodynamic profiles of the different forms of shock were uncovered, a classification based on cardiovascular characteristics, initially proposed in 1972 by Hinshaw and Cox,³¹ came to be accepted by most clinicians. The categories include (1) hypovolemic shock, due to a decreased circulating blood volume in relation to the total vascular capacity and characterized by a reduction of diastolic filling pressures and volumes; (2) cardiogenic shock related to cardiac pump failure due to loss of myocardial contractility/

functional myocardium or structural/mechanical failure of the cardiac anatomy and characterized by elevations of diastolic filling pressures and volumes; (3) extracardiac obstructive shock involving obstruction to flow in the cardiovascular circuit and characterized by either impairment of diastolic filling or excessive afterload; and (4) distributive shock caused by loss of vasomotor control resulting in arteriolar and venular dilation and (after resuscitation with fluids) characterized by increased cardiac output with decreased systemic vascular resistance. We have adapted these categories into an etiologic/physiologic classification of shock that is summarized in Figure 21.1 and Box 21.2. This figure and box represent our current understanding of the causes and typical hemodynamic features of different forms of shock.

Despite this hemodynamic-based categorization system, it is important to note the mixed nature of most forms of clinical shock. Septic shock is nominally considered a form of distributive shock. However, prior to resuscitation with

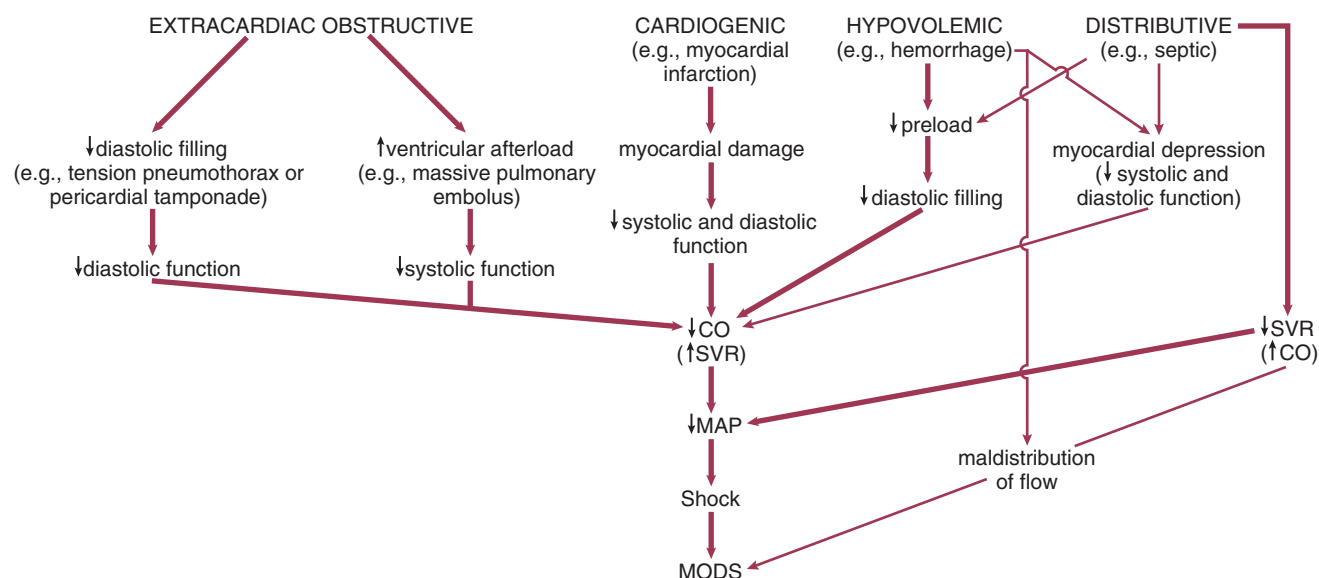

Figure 21.1 The interrelationships among different forms of shock. For cardiogenic, hypovolemic, and obstructive shock, hypotension is primarily due to decreased cardiac output with systemic vascular resistance rising secondarily. With distributive (particularly septic shock), hypotension is primarily due to a decrease in systemic vascular resistance with a secondary increase of cardiac output. In many forms of shock, the hemodynamic characteristics are influenced by elements of hypovolemia, myocardial depression (ischemic or otherwise), and vascular dysfunction (which may affect afterload). Dominant pathophysiologic pathways are denoted by heavier lines. CO, cardiac output; SVR, systemic vascular resistance; MAP, mean arterial blood pressure; MODS, multiple organ dysfunction syndrome.

fluids, a substantial hypovolemic component may exist due to venodilatation and third-spacing. In addition, depression of the myocardium in human septic shock is well documented (see Fig. 21.1).³²⁻³⁴ Similarly, hemorrhagic shock in experimental models has been linked to both myocardial depression^{35,36} and vascular dysfunction (see Fig. 21.1).^{37,38} Cardiogenic shock typically presents with increased ventricular filling pressures. However, many patients have been aggressively diuresed prior to the onset of shock and may have a relative hypovolemic component. In addition, systemic vascular resistance (SVR) is only inconsistently increased in cardiogenic shock, suggesting that an inflammatory element may exist under some circumstances. Finally, shock from any cause may cause a deterioration of the coronary perfusion pressure, the difference between mean arterial pressure (MAP) and the higher of left ventricular diastolic pressure or the right atrial pressure, resulting in some degree of myocardial ischemia and myocardial dysfunction.³⁹ Thus, although four categories of shock exist based on hemodynamic profile, clinical shock states tend to combine components of each.

HYPOVOLEMIC SHOCK

Hypovolemic shock may be related to dehydration, internal or external hemorrhage, gastrointestinal fluid losses (diarrhea or vomiting), urinary losses due to either diuretics or kidney dysfunction, or loss of intravascular volume to the interstitium due to decrease of vascular permeability (in response to sepsis or trauma). In addition, venodilatation due to a number of causes (sepsis, spinal injury, various drugs and toxins) may result in a relative hypovolemic state (see Box. 21.2, Fig. 21.1). Hemodynamically, hypovolemic shock is characterized by a fall in ventricular preload resulting in decreased ventricular diastolic pressures and volumes

(Table 21.1). Cardiac index (CI) and stroke volume index (SVI) are typically reduced. In addition to hypotension, a decreased pulse pressure may be noted. Due to a decreased output and unchanged or increased metabolic demand, mixed venous oxygen saturation (MVO_2) may be decreased and the arteriovenous oxygen content difference widened. Clinical characteristics include pale, cool, clammy skin (often mottled); tachycardia (or if severe shock, bradycardia)^{7,40}; tachypnea; flat, nondistended peripheral veins; decreased jugular venous pulse; decreased urine output; and altered mental status.

A number of factors may influence the development and hemodynamic characteristics of hypovolemic shock in humans. Studies in animals and humans have demonstrated a clear relationship between the degree of circulating blood volume loss and clinical response.⁴¹⁻⁴⁴ Acute loss of 10% of the circulating blood volume is well tolerated, with tachycardia the only obvious sign. CI may be minimally decreased despite a compensatory increase in myocardial contractility. SVR typically increases slightly, particularly if sympathetic stimulation augments mean arterial pressure (MAP). Compensatory mechanisms begin to fail with a 20% to 25% volume loss. Mild to moderate hypotension and decreased CI may be present. Orthostasis (with a blood pressure decrease of 10 mmHg and increased heart rate of 20 to 30 beats/minute) may become apparent. There is a marked increase in SVR and serum lactate may begin to rise. With decreases of the circulating volume of 40% or more, marked hypotension with clinical signs of shock is noted. CI and tissue perfusion may fall to less than half normal. Lactic acidosis is usually present at this stage and predicts a poor outcome.^{45,46} The case fatality rate can exceed 50% in hemorrhagic shock associated with trauma.⁴⁷

The rate of loss of intravascular volume and the preexisting cardiac reserve is of substantial importance in the

development of hypovolemic shock. As an example, whereas an acute blood loss of 1 L in a healthy adult may result in mild to moderate hypotension with a reduced pulmonary artery occlusion pressure (PAOP) and central venous pressure (CVP),⁴² the same loss over a longer period of time may be well tolerated due to compensatory responses such as tachycardia, increased myocardial contractility, increased red blood cell 2,3-diphosphoglycerate (2,3 DPG), and increased fluid retention. On the other hand, a similar slow loss may lead to substantial hemodynamic compromise in a person with a limited cardiac reserve, even while the person's PAOP and CVP remain elevated.

Hypovolemic shock represents more than a simple mechanical response to loss of circulating volume. It is a dynamic process involving competing adaptive (compensatory) and maladaptive responses at each stage of

development. Thus, although intravascular volume replacement is always a necessary component of resuscitation from hypovolemia or hypovolemic shock, the biologic responses to the insult may progress to the point where such resuscitation is insufficient to reverse the progression of the shock syndrome. Patients who have sustained a greater than 40% loss of blood volume for 2 hours or more may be unable to be effectively resuscitated.^{37,41,44} A series of inflammatory mediator, cardiovascular, and organ responses to shock are initiated, which supersede the importance of the initial insult in driving further injury.

CARDIOGENIC SHOCK

Cardiogenic shock results from the failure of the heart as a pump (see Box 21.2, Fig. 21.1). It is the most common cause

Table 21.1 Hemodynamic Profiles of Shock*

Diagnosis	CO	SVR	PWP	CVP	S $\bar{V}O_2$	Comments
Cardiogenic shock						
Caused by myocardial dysfunction	↓↓	↑	↑↑	↑↑	↓	Usually occurs with evidence of extensive myocardial infarction (>40% of left ventricular myocardium nonfunctional), severe cardiomyopathy, or myocarditis
Caused by a mechanical defect						
<i>Acute ventricular septal defect</i>	LVCO ↓↓ RVCO > LVCO	↑	nl or ↑	↑↑	↑ or ↑↑	If shunt is left to right, pulmonary blood flow is greater than systemic blood flow; oxygen saturation “step-up” (≥5%) occurs at right ventricular level; ↑ S $\bar{V}O_2$ is caused by left to right shunt
<i>Acute mitral regurgitation</i>	Forward CO ↓↓	↑	↑↑	↑ or ↑↑	↓	Large V waves (≥10 mm Hg) in pulmonary wedge pressure tracing
Right ventricular infarction	↓↓	↑	nl or ↑	↑↑	↓	Elevated right atrial and right ventricular filling pressures with low or normal pulmonary wedge pressures
Extracardiac obstructive shock						
Pericardial tamponade	↓ or ↓↓	↑	↑↑	↑↑	↓	Dip and plateau in right and left ventricular pressure tracings. The right atrial mean, right ventricular end-diastolic, pulmonary artery end-diastolic, and pulmonary wedge pressures are within 5 mm Hg of each other
Massive pulmonary emboli	↓↓	↑	nl or ↓	↑↑	↓	Usual finding is elevated right-sided heart pressures with low or normal pulmonary wedge pressure
Hypovolemic shock	↓↓	↑	↓↓	↓↓	↓	Filling pressures may appear normal if hypovolemia occurs in the setting of baseline myocardial compromise
Distributive shock						
Septic shock	↑↑ or nl, rarely ↓	↓ or ↓↓	↓ or nl	↓ or nl	↑ or ↑↑	The hyperdynamic circulatory state (↑ CO, ↓ SVR) associated with distributive forms of shock usually depends on resuscitation with fluids; before such resuscitation, a hypodynamic circulation is typical
Anaphylaxis	↑↑ or nl, rarely ↓	↓ or ↓↓	↓ or nl	↓ or nl	↑ or ↑↑	

*The hemodynamic profiles summarized in this table refer to patients with the diagnosis listed in the left column who are also in shock (mean arterial blood pressure < 60–65 mmHg).

CO, cardiac output; CVP, central venous pressure; LV, left ventricular; nl, normal; PWP, pulmonary wedge pressure; SVR, systemic vascular resistance; S $\bar{V}O_2$, mixed venous oxygen saturation; ↑↑ or ↓, mild to moderate increase or decrease; ↑↑ or ↓↓, moderate to severe increase or decrease.

Modified from Parrillo JE: Septic shock: Clinical manifestations, pathogenesis, hemodynamics, and management in a critical care unit. In Parrillo JE, Ayers SM (eds): Major Issues in Critical Care Medicine. Baltimore, Williams & Wilkins, 1984.

of in-hospital mortality in patients with Q-wave myocardial infarction.^{48,49} Hemodynamically, cardiogenic shock is characterized by increased ventricular preload (increased ventricular volumes, pulmonary wedge pressure [PWP] and CVP) (see Table 21.1). Otherwise hemodynamic characteristics are similar to those for hypovolemic shock (see Table 21.1). In particular, both involve reduced CI, SVI, and ventricular stroke work indices with increased SVR. Due to inadequate tissue perfusion, the M $\bar{V}O_2$ is substantially reduced and the arteriovenous oxygen content difference increased. The degree of lactic acidosis may predict mortality.⁵⁰ Clinically, the specific signs of shock are similar. However, signs of congestive heart failure (volume

overload) are typically present in cardiogenic shock. The jugular and peripheral veins may be distended. An S3 and evidence of pulmonary edema are usually found.

Cardiogenic shock is most commonly due to ischemic myocardial injury with a total of 40% of the myocardium nonfunctional.^{49,51–53} Such damage may involve a single large myocardial infarction or may involve accumulation of damage from multiple infarctions. In addition, viable but dysfunctional “stunned” myocardium may temporarily contribute to cardiogenic shock postinfarction. Cardiogenic shock usually involves an anterior myocardial infarction with left main or proximal left anterior descending artery occlusion. Historically, the incidence of cardiogenic shock

due to Q-wave infarction has ranged from 8% to 20%.^{48,54-56} Although several large studies demonstrate lower incidence rates (4% to 7%) when patients receive thrombolytic interventions,^{55,57-60} retrospective community studies suggest no overall decrease in the incidence of postinfarction cardiogenic shock or cardiogenic shock mortality (70% to 90%) in the first decades following the introduction of this therapy.⁴⁸ Further, no trials have demonstrated that thrombolytic therapy reduces mortality rates in patients with established cardiogenic shock.^{60,61} In contrast, several major studies suggest that mortality of infarction-related cardiogenic shock may be improved by emergent angioplasty.^{56,62-64} Accordingly, data suggest a reduction in the incidence of acute infarction-related cardiogenic shock to <2% in 2003 in association with widespread use of emergent percutaneous coronary intervention.⁶² This intervention has also been associated with a reduction of cardiogenic shock mortality risk from 60% to 84% to 43% to 47% in two large analyses.^{56,62}

Mortality is better for cardiogenic shock due to surgically remediable cardiac lesions. Mitral valve failure may be associated with rupture or dysfunction of chordae or papillary muscles due to myocardial ischemia or infarction, endocarditis, blunt chest trauma, or prosthetic valve deterioration and is characterized by “v” waves of greater than 10 mm Hg on a PAOP tracing. Ischemic papillary muscle rupture frequently occurs 3 to 7 days after an infarct in left anterior descending coronary artery territory and may be preceded by the onset of a mitral regurgitant murmur.⁶⁵ Mortality is high in the absence of surgical therapy.⁶⁵ Acute aortic valve failure is most commonly due to endocarditis but may involve mechanical failure of prosthetic valves, or aortic dissection. Ventricular septal defects caused by myocardial infarction may also result in the abrupt onset of cardiogenic shock and can be diagnosed by a 5% step up in hemoglobin oxygen saturation between the right atrium and the pulmonary artery (due to left-to-right shunting of blood through the septum).⁶⁶ As with ischemic papillary muscle rupture, rupture of the intraventricular septum is most frequently seen with occlusions of the left anterior descending artery, a few days after infarction.⁶⁶

The pathophysiology of cardiogenic shock due to a right ventricular infarction and failure is different from other forms of cardiogenic shock. Although some degree of right ventricular involvement is seen in half of inferior myocardial infarctions, only the largest 10% to 20% result in right ventricular failure and cardiogenic shock.⁶⁷ These infarctions usually involve part of the left ventricular wall as well. Isolated infarctions of the right ventricle are rare.^{67,68}

Because therapy of this form of shock requires fluid resuscitation and inotropes (rather than vasopressors), differentiation from other causes of cardiogenic shock is crucial. Conditions compromising right ventricular function such as cardiac tamponade, restrictive cardiomyopathy, constrictive pericarditis, and pulmonary embolus are also included in the differential diagnosis. Each of these conditions may present with some of the typical clinical and hemodynamic findings of right ventricular infarction including Kussmaul’s sign, and pulsus paradoxus with elevation and equalization of CVP, right ventricular systolic pressure, pulmonary artery diastolic pressure, and PAOP. Prognosis in this form of cardiogenic shock is distinctly better than that of cardiogenic shock due to left ventricular infarction^{69,70}; however, an

inferior infarction with right ventricular injury has a substantially worse prognosis than such an infarction without significant right-sided involvement.⁷¹

As with hypovolemic shock, a number of interactions may complicate the development of cardiogenic shock. Optimal cardiac performance in patients with impaired myocardial contractility may occur at substantially higher than normal PAOP (i.e., 20 to 24 mm Hg). Yet patients who develop cardiogenic shock are frequently initially treated with diuretics and may have a degree of hypovolemia (relative to their optimal requirements). Thus, patients should not be diagnosed with cardiogenic shock unless hypotension (MAP < 65 mm Hg) and reduced cardiac output (CI < 2.2 L/min/m²) coexist with an elevated ventricular filling pressure.⁷² Cautious fluid challenge may be required (in the absence of overt pulmonary edema) to increase the filling pressures to an optimal range. Other interactions include increased right ventricular ischemia due to decreased right coronary perfusion pressure (MAP decreased while right ventricular end-diastolic pressure is increased) and increased right ventricular afterload due to pulmonary hypertension. Right ventricular ischemia may also lead to right ventricular dilatation, septal shift, and impairment of left ventricular function.

Other causes of cardiogenic shock include acute myocarditis, end-stage cardiomyopathy, brady- or tachyarrhythmias, hypertrophic cardiomyopathy with obstruction, and traumatic myocardial contusion (see [Box 21.2](#)).

OBSTRUCTIVE SHOCK

Extracardiac obstructive shock results from an obstruction to flow in the cardiovascular circuit (see [Box 21.2](#), [Fig. 21.1](#)). Pericardial tamponade and constrictive pericarditis directly impair diastolic filling of the right ventricle. Tension pneumothorax and intrathoracic tumors indirectly impair right ventricular filling by obstructing venous return. Massive pulmonary emboli (two or more lobar arteries with >50% of the vascular bed occluded), nonembolic acute pulmonary hypertension, large systemic emboli (e.g., saddle embolus), and aortic dissection may result in shock due to increased ventricular afterload.

The characteristic hemodynamic/metabolic patterns are, in most ways, similar to other low output shock states (see [Table 21.1](#)). CI, SVI, and stroke work indices are usually decreased. Because tissue perfusion is decreased, the MVO₂ is low, the arteriovenous oxygen content difference increased, and serum lactate frequently elevated. Other hemodynamic parameters are dependent on the site of the obstruction. Tension pneumothorax and mediastinal tumors may obstruct the great thoracic veins, resulting in a hemodynamic pattern (decreased CI and elevated SVR) similar to hypovolemia (although distended jugular and peripheral veins may be seen). Cardiac tamponade typically causes increased and equalized right and left heart ventricular diastolic pressures, pulmonary artery diastolic pressure, CVP, and PAOP. In constrictive pericarditis, right and left ventricular diastolic pressures are elevated and within 5 mm Hg of each other. Mean right and left atrial pressures may or may not be equal as well. Massive pulmonary embolus will result in right ventricular failure with elevated pulmonary artery and right heart pressures whereas PAOP remains normal. A systemic saddle embolus or aortic occlusion

due to dissection causes peripheral hypotension and signs of left ventricular failure including an elevated PAOP. Clinical signs are similarly dependent on the site of the obstruction.

As with other forms of shock, the time course of development of the insult has a substantial impact on the clinical response. Ischemic rupture of the left ventricular free wall (usually 3 to 7 days after myocardial infarction) leads to immediate cardiac tamponade and shock with as little as 150 mL blood in the pericardium.⁷³⁻⁷⁵ Survival requires emergency surgery.^{74,75} Similar situations may develop with bleeding into the pericardium after blunt chest trauma or thrombolytic therapy. Pericardial tamponade due to malignant or inflammatory pericardial effusions usually develop much more slowly. Although shock may still develop, it usually requires substantially more pericardial fluid (1 to 2 L) to cause critical failure of right ventricular diastolic filling.⁷³ No large reliable studies examining mortality rates with and without therapy in these conditions are available due to the small numbers of cases.

A similar time course–dependent risk is seen with major pulmonary emboli. In those without preexisting cardiopulmonary disease, a massive embolus involving two or more lobar arteries and 50% to 60% of the vascular bed^{76,77} may result in obstructive shock. However, if recurrent smaller pulmonary emboli result in right ventricular hypertrophy, a substantially larger total occlusion of the pulmonary vascular bed may be required to cause right ventricular decompensation. Analyses have suggested that the presence of shock due to pulmonary embolus (regardless of underlying chronic cardiopulmonary dysfunction) indicates a three- to sevenfold increase in mortality risk with the majority of deaths occurring within an hour of presentation.^{78,79} An analysis of more than 70,000 unstable (hemodynamic instability or ventilator-requiring) patients with pulmonary embolus in the national inpatient sample shows that mortality in untreated patients is approximately 47%.⁸⁰ Systemic thrombolysis is associated with a substantial reduction in mortality to 15%. Where available, catheter-directed therapy may be even more efficacious with a lower risk of serious hemorrhage.⁸¹ Shock due to pulmonary embolism is an indication for urgent thrombolytic or catheter-directed intervention.

DISTRIBUTIVE SHOCK

The defining feature of distributive shock is loss of peripheral resistance. Septic shock is the most common form and has the greatest impact on intensive care unit (ICU) morbidity and mortality.

Hemodynamically, distributive shock is characterized by an overall decrease in SVR (see Table 21.1). However, resistance in any specific organ bed or tissue may be decreased, increased, or unchanged. Initially, CI may be depressed and ventricular filling pressures decreased. After fluid resuscitation, when filling pressures are normalized or increased, CI is usually elevated. Due to hypotension, left and right ventricular stroke work indices are normally decreased. MVO_2 is increased above normal. Concomitantly, arteriovenous oxygen content difference is narrowed despite the fact that oxygen demand is usually increased (particularly in sepsis). The basis of this phenomenon may be that because total

body perfusion (CI) is increased, perfusion is not effective in that either it does not reach the necessary tissues or the tissues cannot utilize the substrates presented. As a reflection of this inadequate “effective” tissue perfusion, lactic acidosis may ensue. Clinical characteristics of resuscitated distributive shock include, in contrast to the other forms of shock, warm, well-perfused extremities, a decreased diastolic blood pressure, and an increased pulse pressure. Nonspecific signs of shock include tachycardia, tachypnea, decreased urine output, and altered mentation. In addition, evidence of the primary insult may exist (urticaria for anaphylaxis, spinal injury for neurogenic shock, and evidence of infection in septic shock).

Septic shock (shock due to infection) and sepsis-associated multiple organ failure are the most common causes of death in ICUs of the industrialized world. As many as 800,000 cases of sepsis are admitted every year to American hospitals (comparable to the incidence of first myocardial infarctions) with half of those developing septic shock and about half of those (200,000) dying.⁸² Since the 1970s there has been a progressive increase in the incidence of and total deaths from sepsis and septic shock.⁵ The total toll of septic deaths is comparable to deaths from myocardial infarction and far exceeds the impact of illnesses such as AIDS or breast cancer.^{82,83}

Septic shock is caused by the systemic activation of the inflammatory cascade. Numerous mediators including cytokines, kinins, complement, coagulation factors, and eicosanoids are activated or systemically released, resulting in profound disturbances of cardiovascular and organ system function⁸⁴ (Table 21.2). These mediators, particularly tumor necrosis factor α (TNF α), interleukin-1 β (IL-1 β), platelet activating factor (PAF), and prostaglandins are thought to mediate reduced peripheral vascular resistance seen in septic shock.

Loss of vascular autoregulatory control may explain some of the typical metabolic findings of sepsis and septic shock. An early theory postulated the existence of microanatomic shunts between the arterial and venous circulations. During sepsis, these shunts were said to result in decreased SVR and increased MVO_2 .⁸⁵ However, although microanatomic shunting has been noted in localized areas of inflammation, systemic evidence of this phenomenon in sepsis and septic shock is lacking.⁸⁵⁻⁸⁹ “Functional” shunting due to defects of microcirculatory regulation in sepsis has also been suggested.^{90,91} Overperfusion of tissues with low metabolic requirements would increase MVO_2 and narrow the arteriovenous oxygen content difference. Relative vasoconstriction of vessels supplying more metabolically active tissues would result in tissue hypoxia and lactate production due to anaerobic metabolism. Observations that some capillary beds may be occluded by platelet microaggregates, leukocytes, fibrin deposits, and endothelial damage support this theory.^{86,90,92} Additional support comes from studies that demonstrate evidence of oxygen supply–dependent oxygen consumption in sepsis.⁹³⁻⁹⁷ A third theory suggests that circulating mediators cause an intracellular metabolic defect involving substrate utilization, which results in bioenergetic failure (decreased high-energy phosphate production) and lactate production.^{98,99} Increased mixed venous oxygen saturation could then be explained by perfusion, which is increased in excess of tissue oxygen utilization capability. However,

Table 21.2 Inflammatory Mediators in Sepsis and Septic Shock

Mediator	Major Reported Effects
Pro-inflammatory Cytokines	
Tumor necrosis factor- α (TNF α)	<p>Stimulates release of interleukin-1, interleukin-6, interleukin-8, platelet-activating factor, leukotrienes, thromboxane A₂, prostaglandins; may be able to stimulate macrophages directly to promote its own release</p> <p>Stimulates production of polymorphonuclear cells by bone marrow; enhances phagocytic activity of polymorphonuclear cells</p> <p>Promotes adhesion of endothelial cells, polymorphonuclear cells, eosinophils, basophils, monocytes, and, occasionally, lymphocytes by inducing increased expression of adhesion molecules</p> <p>Activates common pathway of coagulation and complement system</p> <p>Directly toxic to vascular endothelial cells; increases microvascular permeability</p> <p>Acts directly on hypothalamus to produce fever</p> <p>Reduces transmembrane potential of muscle cells and depresses myocardial contractility</p> <p>Decreases arterial pressure, systemic vascular resistance, and ventricular ejection fraction; increases cardiac output</p>
Interleukin-1 β (IL-1 β)	<p>Stimulates release of TNF, interleukin-6, interleukin-8, platelet-activating factor, leukotrienes, thromboxane A₂, prostaglandins; may also be capable of stimulating its own production</p> <p>Activates resting T cells to produce lymphocytes and other products; supports B-cell proliferation and antibody production; is cytotoxic for insulin-producing B cells</p> <p>Promotes adhesion of endothelial cells, polymorphonuclear cells, eosinophils, basophils, monocytes, and, occasionally, lymphocytes by inducing increased expression of adhesion molecules</p> <p>Promotes polymorphonuclear cell activation and accumulation</p> <p>Increases endothelial procoagulant activity</p> <p>Acts synergistically with TNF; enhances tissue cell sensitivity to TNF</p> <p>Depresses myocardial contractility</p> <p>Acts directly on hypothalamus to produce fever</p>
Interleukin-2	<p>May promote release of TNF and interferon-gamma</p> <p>Decreases arterial pressure, systemic vascular resistance, and ejection fraction; increases cardiac output</p>
Interleukin-4	<p>Enhances lymphocyte adhesion to endothelial cells</p> <p>Induces antigen expression on macrophages</p> <p>Synergistically increases TNF- or interleukin-1-induced antigen expression on endothelial cells, but inhibits the increased expression of adhesion molecules by TNF, interleukin-1, or interferon-gamma</p>
Interleukin-6	<p>Induction of hepatic acute phase protein response</p> <p>Induces myelomonocytic and terminal B lymphocyte differentiation; activates T cells/thymocytes</p> <p>May contribute to septic myocardial depression</p> <p>Inhibits TNF production</p>
Interleukin-8	<p>Chemotactic for both neutrophils and lymphocytes; induces tissue infiltration of both</p> <p>Inhibits endothelial-leukocyte adhesion; decreases the hyperadhesion induced by those molecules</p>
Interleukin-17	Induces synthesis of TNF- α , IL-1 β , IL-6, G-CSF, GM-CSF, TGF- β , and other chemokines
Interleukin-18	Initiates cell-mediated immune response
Interferon- γ	<p>Increases secretion of interferon-γ</p> <p>Promotes release of TNF, interleukin-1, interleukin-6 (possibly due to its ability to augment effects of endotoxin on macrophages); augments production of adhesion molecules</p> <p>May act synergistically with TNF to produce cytotoxic and cytostatic activity; interacts with other cytokines in variable ways</p> <p>Encourages polymorphonuclear cell activation and accumulation; enhances the phagocytic activity of polymorphonuclear cells</p> <p>Promotes macrophage activation, macrophage microbicidal function, and expression of cellular receptors for TNF-α</p>
Macrophage migration inhibitory factor (MIF)	<p>Increases TNF-α and TLR4 expression</p> <p>Activates T-lymphocytes</p> <p>Increases mortality in experimental peritonitis</p>
High-mobility group box protein-1 (HMGB1)	<p>Possesses both cytokine and intracellular signaling activity</p> <p>May generate late organ failure of sepsis</p> <p>Impairs vascular endothelial integrity</p>

Table 21.2 Inflammatory Mediators in Sepsis and Septic Shock (Continued)

Mediator	Major Reported Effects
Anti-inflammatory Cytokines	
Interleukin-4	Induction of differentiation of naïve helper T cells to Th2 cells
Interleukin-10	Down-regulation of macrophage function, leading to decreased TNF- α release
Interleukin-1 receptor antagonist (IL-1RA)	Antagonistic blockade of IL-1 β
Transforming growth factor β 1 (TGF β)	Broad immunomodulatory activity (protective in endotoxic shock) Inhibition of effect of proinflammatory cytokines on a variety of tissues Suppression of macrophage pro-inflammatory responses Interference with phagocytic activation
Endothelial Factors	
Endothelin 1	Strongly promotes vasoconstriction
Nitric oxide	Mediates vascular smooth muscle relaxation and arteriovenular dilatation in septic shock May be responsible for septic myocardial depression Involved in leukocyte/macrophage antimicrobial activity
Arachidonic Acid Pathway Factors and Metabolites	
Phospholipase A ₂	Releases arachidonic acid (the precursor of eicosanoids such as leukotrienes, prostaglandins, and thromboxanes) Decreases arterial pressure, systemic vascular resistance, and ventricular ejection fraction; increases cardiac output
Leukotrienes	Promote neutrophil chemotaxis and adhesion of neutrophils to endothelium (neutrophils have specific receptors for leukotriene B ₄) Increase vascular permeability, either directly or through interaction of neutrophils and endothelial cells
Thromboxane A ₂	Decrease coronary blood flow and myocardial contractility Produces vasoconstriction of vascular beds; secondarily promotes release of endothelium-derived relaxing factor and may stimulate prostacyclin production Causes platelet aggregation and neutrophil accumulation Increases vascular permeability; enhances permeability of both single- and double-unit membranes
Prostaglandin E ₂	Produces pulmonary bronchoconstriction Inhibits interleukin-1 production Low concentrations stimulate TNF release; higher concentrations suppress TNF production at a dose-dependent level Causes vasodilation and increased blood flow Has a beneficial effect on tissue perfusion and may thereby decrease the severity of tissue damage Acts synergistically with prostacyclin to increase the effects of serotonin and bradykinin on vascular permeability
Prostacyclin (prostaglandin I ₂)	Inhibits platelet aggregation and adhesion Causes vasodilation and increased blood flow; in early sepsis, exerts a beneficial effect on tissue perfusion Produces smooth muscle relaxation
Others	
Platelet-activating factor	Stimulates release of TNF, leukotrienes, thromboxane A ₂ Promotes leukocyte activation and subsequent free-radical formation Encourages platelet aggregation leading to thrombosis Markedly alters microvascular permeability, thereby promoting microvascular fluid loss Exerts a negative inotropic effect on the heart; lowers arterial blood pressure
Complement fragment C3a	Causes mast cell degranulation and vasodilatory mediator release
Fragment C5a	Causes smooth muscle contraction and mucous secretion Causes mast cells to degranulate and release vasodilatory mediators Promotes TNF release Enhances polymorphonuclear cell activation, migration, adherence, and aggregation Induces capillary leakage May decrease systemic vascular resistance and produce hypotension

Adapted from Bone RC: The pathogenesis of sepsis. *Ann Intern Med* 1991;115:457.

animal studies using nuclear magnetic resonance (NMR) spectroscopy demonstrate that high-energy phosphates are not depleted in septic animals as is expected in all of these theories.¹⁰⁰⁻¹⁰² According to these and other studies, cellular ischemia is not the dominant factor in metabolic dysfunction in sepsis.¹⁰⁰⁻¹⁰⁶ Rather, circulating mediators may result in cellular dysfunction, aerobic glycolysis, and lactate production in the absence of global ischemia.¹⁰¹ This position is weakened by data suggesting that increased lactate in septic shock is also associated with decreased pH (which would not be expected in aerobic glycolysis)¹⁰¹ and, to some extent, by studies that support the existence of oxygen supply-dependent oxygen consumption in sepsis.⁹⁴⁻⁹⁷

The trigger for systemic activation of the inflammatory cascade is the presence of gram-negative bacilli in 50% to 75% of cases of septic shock. Gram-positive bacteria account for most of the remainder, but infection with fungi, protozoa, and viruses can also result in septic shock.¹⁰⁷⁻¹⁰⁹ Investigations suggest a surprising commonality of signaling mechanisms in septic shock via Toll-like receptors from a broad range of etiologic agents.¹¹⁰⁻¹¹⁴ Despite aggressive supportive care and antibiotic treatment, mortality is 50% overall and may exceed 70% for gram-negative septic shock.¹⁰⁷ Of those succumbing to septic shock, approximately 75% are early deaths (within 1 week of shock), primarily due to hyperdynamic circulatory failure.¹¹⁵ Late mortality is usually due to MODS.¹¹⁵

More than any other form of shock, distributive and, particularly, septic shock involves substantial elements of the hemodynamic characteristics of other shock categories (see Fig. 21.1, Table 21.1). As noted, all forms of distributive shock involve decreased mean peripheral vascular resistance. Prior to fluid resuscitation, distributive shock also involves a relative hypovolemic component. The first element of this relative hypovolemia is an increase of the vascular capacitance due to venodilatation. This phenomenon has been directly supported in animal models of sepsis¹¹⁶⁻¹²⁰ and is reinforced by the fact that clinical hypodynamic septic shock (low cardiac output) can usually be converted to hyperdynamic shock (high cardiac output) with adequate fluid resuscitation.^{115,121,122} Relaxation of vascular smooth muscle is attributed to a number of the mediators known to circulate during sepsis. These same mediators also contribute to the second cause of hypovolemia in sepsis, third-spacing of fluid to the interstitium due to a loss of endothelial integrity. In addition, a number of studies have demonstrated that human septic shock is characterized by myocardial depression (biventricular dilatation and decreased ejection fraction).³²⁻³⁴ Circulating substances such as TNF α , IL-1 β , platelet activating factor (PAF), leukotrienes, and, most recently, interleukin-6 (IL-6) have been implicated in this process.¹²³⁻¹³⁰

Anaphylactic shock is a form of distributive shock caused by the release of mediators from tissue mast cells and circulating basophils. Anaphylaxis, an immediate hypersensitivity reaction, is mediated by the interaction of IgE antibodies on the surface of mast cells and basophils with the appropriate antigen. Antigen binding results in the release of the primary mediators of anaphylaxis contained in the basophilic granules of mast cells and basophils. These include histamine, serotonin, eosinophil chemotactic factor, and various proteolytic enzymes.¹³¹ Subsequently, a number of

secondary lipid mediators are synthesized and released including PAF, bradykinin prostaglandins, and leukotrienes (slow-reacting substance of anaphylaxis).¹³¹ An anaphylactoid reaction (clinically indistinguishable from anaphylaxis) results from the direct, nonimmunologic release of mediators from mast cells and basophils and can also result in shock.

Anaphylaxis is triggered by insect envenomations (*Hymenoptera* bees, hornets, and wasps) and certain drugs, especially antibiotics (beta-lactams, cephalosporins, sulfonamides, vancomycin).¹³¹ In addition, less frequently, heterologous serum (e.g., tetanus antitoxin, snake antitoxin, antilymphocyte antisera), blood transfusion, immunoglobulin (particularly in IgA-deficient patients), and egg-based vaccine products have been implicated.¹³¹ Anaphylactoid reactions can be caused by a wide range of medical agents including ionic contrast media, protamine, opiates, polysaccharide volume expanders such as dextran and hydroxyethyl starch, muscle relaxants, and anesthetics.¹³¹

The hemodynamic features of anaphylactic shock are very similar to those for septic shock and include elements of hypovolemia (due to interstitial edema and venodilatation) and myocardial depression.¹³²⁻¹³⁶ Cardiac output and ventricular filling pressures may be reduced until patients are fluid resuscitated.^{136,137} In addition to typical findings of shock, patients may demonstrate urticaria, angioedema, laryngeal edema, and severe bronchospasm.

Neurogenic shock involves the loss of peripheral vasomotor control due to dysfunction or injury of the nervous system. The classic example is shock associated with spinal injury. A similar phenomenon is active in vasovagal syncope and spinal anesthesia, but such conditions are self-limited and transient. The major cause of shock in spinal injury appears to be loss of venous tone resulting in increased venous capacitance. Arteriolar tone may also be affected, resulting in increased cardiac output after fluid resuscitation.

Adrenal crisis (see also Chapter 59) is an uncommon cause of shock, which can be difficult to diagnose as it occurs in patients with other active disease processes and the clinical features may mimic infection. It is a life-threatening emergency that requires prompt diagnosis and management.

Adrenal crisis is caused by a deficiency of adrenal production of mineralocorticoids and glucocorticoids. It may occur de novo in patients with critical illness or may occur against a background of occult adrenal insufficiency. In the critical care setting, the most common cause of de novo acute adrenal insufficiency is bilateral adrenal hemorrhage in association with overwhelming infections (classically meningococcal, but frequently gram-negative bacteria), human immunodeficiency virus infection, or anticoagulation.^{138,139} In addition, fungal infections such as histoplasmosis, blastomycosis, and coccidioidomycosis and malignant infiltration of the adrenals may cause acute adrenal insufficiency in ICU patients.¹³⁹ In some patients, steroid production remains adequate for the baseline state despite adrenal disease. Once stressed, however, the adrenal response is inadequate, leading to decompensation and adrenal crisis. Stressors may be relatively innocuous or may be severe. A febrile illness, infection, trauma, surgery, dehydration, or any other intercurrent illness may trigger the crisis. Abrupt cessation of

glucocorticoid therapy or replacement may also result in adrenal crisis.

Symptoms are generally nonspecific and may include anorexia, nausea, vomiting, diarrhea, abdominal pain, myalgia, joint pains, headache, weakness, confusion, and agitation or delirium.^{139,140} Fever (often out of proportion to any minor infection) is almost always present, and hypotension, initially due to hypovolemia, is frequent.¹³⁹ The initial hemodynamic pattern may resemble hypovolemic shock (if shock is due only to adrenal crisis). With volume resuscitation, a high output, vasopressor-refractory shock may become apparent.^{141,142}

Shock due to adrenal crisis may be masked by or contribute to shock due to other concomitant critical illnesses, particularly septic shock. Thus, if vasopressor-refractory shock occurs in patients potentially predisposed to adrenal insufficiency, a cortisol level and rapid adrenocorticotrophic hormone (ACTH) stimulation test must be performed and the patient given glucocorticoids and other therapy.

An unrecognized “relative” adrenal insufficiency has been implicated in the pathogenesis of human septic shock.¹⁴³⁻¹⁴⁷ In this circumstance, sepsis is associated with a suboptimal adrenal response with an improvement in cardiovascular parameters or outcome with “stress” dose corticosteroid administration.^{143,145,146,148,149} One randomized controlled trial has suggested that prospective “stress dose” therapy with a combination of hydrocortisone (50 mg intravenous every 6 hours) and fludrocortisone (50 µg oral/nasogastric daily) for 7 days improved outcome in nonresponders to corticotropin challenge.¹⁵⁰ Unfortunately, confirmatory randomized trials have failed to reproduce this finding.^{151,152}

COMPENSATORY RESPONSES TO SHOCK

Shock is usually not a discrete condition occurring abruptly after injury or infection. With the onset of hemodynamic stress, homeostatic compensatory mechanisms engage to maintain effective tissue perfusion. At this time, subtle clinical evidence of hemodynamic stress may be apparent (tachycardia, decreased urine output), but overt evidence of shock (hypotension, altered sensorium, metabolic acidosis) may not. Therapeutic interventions have a high probability of preventing ischemic tissue injury and initiation of systemic inflammatory cascades during this early compensated stage. Adaptive compensatory mechanisms fail and organ injury ensues if the injury that initiates shock is too extensive or progresses despite therapy. As the duration of established shock increases, therapy is less likely to be effective in preventing organ failure and death.

Various sensing mechanisms involved in physiologic compensatory responses exist to recognize hemodynamic and metabolic dyshomeostasis (Fig. 21.2). Low-pressure right atrial and pulmonary artery stretch receptors sense volume changes. A decrease in circulating volume (or an increase of venous capacitance) results in an increase in sympathetic discharge from the medullary vasomotor center.^{153,279,280} Aortic arch, carotid, and splanchnic high pressure baroreceptors sense early blood pressure changes close to the physiologic range.^{153,279,280} An increase of sympathetic discharge from the medullary vasomotor center results from a small to moderate decrease in blood pressure associated with early shock. However, once mean arterial pressure falls

below about 80 to 90 mm Hg, aortic baroreceptor activity is absent. Subsequently, carotid baroreceptor response is eliminated as mean pressure falls below 60 mm Hg. As blood pressure falls further, carotid and aortic chemoreceptors, sensitive to decreased PO_2 , increased PCO_2 , and increased hydrogen ion concentrations (decreased pH), dominate the response. These receptor complexes, active only when mean blood pressure is less than approximately 80 mm Hg, are of minimal relevance during physiologic states.¹⁵³ During shock, they make a substantial contribution to increases of sympathetic tone.

During severe shock, the most powerful stimulus to sympathetic tone is the central nervous system ischemic response.¹⁵³ The lower medullary chemoreceptors for this response (thought to be sensitive to increased CO_2 associated with decreased cerebral perfusion) become active when mean blood pressure falls below 60 mm Hg. Sympathetic stimulation provided by these receptors peaks at mean pressures of 15 to 20 mm Hg and results in maximal stimulation of the cardiovascular system.¹⁵³ The Cushing response to increased intracranial pressure is an example of activation of this reflex under different circumstances.

Other mechanisms also play a role in the compensatory response to shock. Vasopressin release is regulated by alterations of serum osmolality. During effective hypovolemia due to intravascular volume loss or increased vascular capacitance, low-pressure, right atrial stretch receptors can override osmolar control of vasopressin response to result in the retention of body water.^{153,281} Similarly, during hypovolemia and shock, the juxtaglomerular apparatus in the kidneys responds to decreased perfusion pressure by renin release.¹⁵³

All compensatory responses to shock, whether hemodynamic, metabolic, or biochemical, support oxygen delivery to vital organs. These responses are similar (to varying extents) for different classes of shock and can be broken down into four components: (1) preserving mean circulatory pressure (a measure of venous pressure) by either maintaining total intravascular volume or increasing stressed volume (i.e., increasing venous tone), (2) optimizing cardiac performance, (3) redistributing perfusion to vital organs, and (4) optimizing the unloading of oxygen at the tissues (Box 21.3, Fig. 21.E3).

Mean circulatory pressure and venous return are sustained in early shock by a number of mechanisms. Acutely, total intravascular volume is supported by alterations of capillary hydrostatic pressure as described by Starling.²⁸² Sympathetic activation results in precapillary vasoconstriction. In combination with initial hypotension, this results in decreased capillary hydrostatic pressure.²⁸² A decrease in capillary hydrostatic pressure enhances intravascular fluid shift due to maintained plasma oncotic pressures. Transcapillary fluid influx following the removal of 500- to 1000-mL blood volumes in humans can be as high as 2 mL/minute with full correction of intravascular volume by 24 to 48 hours.²⁸³ The intravascular volume may also be supported by the osmotic activity of glucose generated by glycogenolysis. Increased extracellular osmolality results in fluid redistribution from the intracellular to the extracellular space.

Intravascular volume is also conserved by decreasing renal fluid losses. Renal compensatory mechanisms are of limited value in acute shock but can have more impact in the subacute phase. Decreased renal perfusion associated with reduced cardiac output and afferent arteriolar

PATHOGENESIS AND PATHOPHYSIOLOGY OF SHOCK

The inability of cells to obtain or utilize oxygen in sufficient quantity to optimally meet their metabolic requirements has classically been considered to be the pathophysiologic basis of all forms of shock. In the first half of the twentieth century, the study of shock focused on the relatively distinct hemodynamic physiology, which characterizes the different forms of shock. Since then, evidence has accumulated that the various types of clinical shock have significant overlap in their hemodynamic characteristics. In parallel, shock of most etiologies has been shown to involve similar biochemical and metabolic pathways. In the following section, the pathophysiology and pathogenesis of shock will be reviewed from the hemodynamic to the molecular level.

HEMODYNAMIC BASIS OF SHOCK

From a hemodynamic perspective, shock is the failure of cardiovascular adaptation to systemic dyshomeostasis induced by trauma, infection, or other insult such that cardiac output or blood pressure are compromised. This failure is manifested by inadequate organ and tissue perfusion. Although effective perfusion also depends on microcirculatory and intracellular factors (see [Box 21.1](#)), the hemodynamic aspects of shock can be described, in part, by the contributions of cardiac and arterial vascular function to blood pressure and cardiac output.

ARTERIAL PRESSURE

Although cardiac output may be expressed as a function of MAP and vascular resistance ($CO = [MAP - CVP]/SVR$), cardiac output is not directly dependent on MAP in most physiologic states. Instead, blood pressure is typically dependent on cardiac output and vascular resistance. Blood pressure, however, does provide a mechanism to indirectly sense cardiac output and global perfusion perturbations for autoregulatory purposes.

The ability of all organ vascular beds to support normal blood flow depends on the maintenance of blood pressure within the defined range for that organ ([Fig. 21.E1](#)).¹⁵³ Vital organs such as the brain and heart, in particular, are able to autoregulate blood flow over a wide range of blood pressure. Failure to maintain the minimal MAP and perfusion pressure required for autoregulation during hypodynamic circulatory shock indicates a severe reduction in cardiac output. Pharmacologic support of blood pressure in such situations (with alpha-adrenergic agonists) usually results in decreased total systemic perfusion as sensitive vascular beds constrict and overall vascular resistance increases. However, due to their strong autoregulatory capacity, vital organs maintain increased perfusion under these conditions.

In addition to sufficient cardiac output, effective perfusion requires appropriate distribution of blood flow. Failure to maintain blood pressure within the autoregulatory range results in a distribution of blood flow that strictly depends on the passive mechanical properties of the vasculature.¹⁵⁴ This may result in inappropriate distribution of perfusion between and within tissues and organs. Late hemorrhagic shock has been shown to be characterized by

Figure 21.E1 Idealized representation of blood flow autoregulation. Within the autoregulatory range of blood pressure for a tissue or organ, perfusion can be held relatively constant. Outside this range, autoregulation fails and perfusion becomes a function of mean arterial pressure.

abnormal microvascular flow with dilatation of precapillary sphincters.³⁷

CARDIAC OUTPUT

The fact that total systemic perfusion is defined by cardiac output underlies its importance in shock. The product of heart rate and stroke volume determines cardiac output ($CO = \text{heart rate [HR]} \times \text{stroke volume [SV]}$). Stroke volume (a measure of myocardial performance) is dependent on preload, afterload, and contractility.

Preload represents the extent of precontraction myocardial fiber (or sarcomere) stretch. In vivo, preload is the end-diastolic ventricular volume. Because measurement of such volumes in the clinical context is difficult, intracardiac pressures, which can be determined more easily, are frequently substituted. There are difficulties with this approach. The relationship of ventricular end-diastolic volume (preload) to end-diastolic pressure is nonlinear. Further, alterations of myocardial compliance render CVP and PAOP unreliable as estimates of preload in critically ill patients.¹⁵⁵

Preload is dependent on circulating volume, venous tone, atrial contraction, and intrathoracic pressure among other factors.^{153,156} Atrial contraction is particularly important in those with impaired ventricular function. Although it accounts for only 5% to 10% of cardiac output in healthy humans, synchronized atrial contraction contributes as much as 40% to 50% of the cardiac output in patients with severe left ventricular dysfunction.¹⁵⁶ Increased intrathoracic pressure or increased venous capacitance affects preload by reducing venous return.^{153,157} Nitrovasodilators such as nitroglycerin may decrease cardiac output despite arteriolar vasodilation due to their venodilatory (decreased preload) effects. Conversely, the earliest increases in cardiac output seen with sympathetic stimulation and exogenous catecholamine infusion are related to venoconstriction-induced increases of venous return and preload.¹⁵⁸ Cardiogenic and some forms of obstructive shock are typically characterized by increased preload. Preresuscitation distributive shock and hypovolemic shock are uniformly associated with decreased preload.

Afterload refers to the total resistance to the ejection of blood from the ventricle during contraction. Increasing

afterload results in decreased extent and velocity of myocardial contraction. Excessive afterload (aortic dissection, pulmonary embolus) causes some forms of obstructive shock. Ex vivo, afterload can be easily defined as a resistive force applied to an isolated papillary muscle. Because the heart does not displace a fixed mass but rather rhythmically moves a viscous, non-newtonian fluid through branching viscoelastic conduits, the definition of afterload in vivo is difficult.

Afterload has been suggested to be equivalent to systolic myocardial wall stress. This definition suggests that afterload is substantially dependent on intrinsic cardiac mechanical and functional properties.¹⁵⁹ An alternative approach equates left ventricular afterload with the mechanical properties of the arterial side of the circulatory system. Aortic input impedance, which represents the total resistance to flow from outside the left ventricle, is determined by the inertial and viscous properties of blood and the resistive and viscoelastic properties of the arterial system. The term covers SVR, heart rate effects, and pulse wave reflections in the arterial tree.¹⁵⁹ Although it is an accurate measure of afterload in pulsatile systems, assessment of impedance is technically difficult, requiring continuous harmonic analysis of rhythmic variations of aortic pressure and flow. Systemic vascular resistance is a limited approximation of aortic input impedance based on a model that assumes nonpulsatile flow. At a heart rate of 0, SVR and aortic input impedance are equivalent. From a clinical point of view, SVR is the most practical way of assessing afterload.

Afterload is increased in pathologic conditions such as aortic stenosis, systemic embolism, and hypertension. Vasopressors including α -agonists (e.g., phenylephrine, norepinephrine) and vasopressin also increase afterload, whereas nitrates and other vasodilator agents decrease it. Increased intrathoracic pressure due to mechanical ventilation and positive end-expiratory pressure (PEEP) decrease left ventricular afterload while increasing right ventricular afterload. Hypodynamic and hyperdynamic shock are usually characterized by increased and decreased afterload, respectively.

Contractility refers to the intrinsic ability of myocardial fibers to shorten under given loading conditions. Under normal conditions, determinants of contractility include myocardial mass and sympathoadrenal activation state. In pathologic states (e.g., shock), hypoperfusion/ischemia, myocardial cell injury (e.g., reperfusion injury, myocarditis), acidosis, and circulating myocardial depressant substances (such as seen in sepsis) depress cardiac contractility (Fig. 21.E2).

As with preload and afterload, the ex vivo/in vitro assessment of contractility is straightforward. Assessment of in vivo contractility (even in experimental animals) is substantially more difficult due to the intrinsic lability of preload and afterload. Relatively load-independent variables such as peak systolic pressure/end-systolic volume ratio may be the most clinically useful measures of contractility.¹⁶⁰ Many of these variables can be obtained echocardiographically.

VENOUS FUNCTION IN SHOCK

Given that the cardiovascular circuit is a closed system and cardiac output cannot exceed the rate of return of blood to the right ventricle, venous return can be considered a fundamental determinant of cardiac performance. Although

Figure 21.E2 Cardiac function curve demonstrating the effect of variations of preload (atrial pressure), contractility, and afterload on cardiac performance.

preload is a related variable, it primarily reflects ventricular properties related to compliance and heart rate, whereas venous return is substantially dependent on the extracardiac properties of the systemic venous circulation. Maximum venous return is described by the equation:

$$(P_{mc} - P_a) / R_v \quad [1]$$

where P_{mc} is the mean circulatory pressure (the upstream driving pressure of the systemic venous circulation, i.e., the intravascular pressure measured when the heart is stopped), P_a is the right atrial pressure (the downstream pressure that opposes flow to the right ventricle), and R_v is the venous resistance (resistance of the conduit to flow). P_{mc} equals the stressed volume or V_s portion of the vascular volume, which contributes to venous pressure, divided by the mean vascular compliance (C):

$$P_{mc} = V_s / C \quad [2]$$

Stressed volume is dependent on total vascular volume (V_t) and the state of venous tone (i.e., venoconstriction). It is defined as the difference between V_t and the unstressed vascular volume (V_o), the intravascular volume that remains when the vascular circuit is equalized to atmospheric pressure (i.e., the volume remaining after passive exsanguination). Stressed volume is approximately 30% of total blood volume in both humans and experimental animals.¹⁶¹⁻¹⁶³ Compliance refers to the total elastic properties of the entire cardiovascular circuit inclusive of the heart and vasculature.

As Equation 1 shows, the only direct role the heart plays on venous return is to alter right atrial pressure (P_a). Mean arterial pressure has no direct effect at all despite the fact that it is closely related to cardiac output in the systemic circulation ($MAP - CVP = CO \times SVR$).

Rapid alterations of venous return are typically mediated by changes of V_s , P_{mc} or R_v . P_{mc} is acutely influenced by changes of V_s , either directly through alterations of venous capacitance, which primarily involves changes of small vein and venular tone (exogenous vasopressors or vasodilators, sympathetic stimulation), or indirectly by changes of V_t (volume depletion or infusion). Compliance is substantially a passive mechanical property of the vasculature and does

not cause acute alterations of Pmc or venous return. Venous resistance (Rv) to flow is acutely altered by changes of the caliber of large diameter veins, particularly the vena cava and great veins of the thorax. However, although resistance resides primarily in large veins and the vena cava, and venous capacitance resides primarily in small veins and venules, all veins contribute to resistance and capacitance to some extent. Alterations of venous tone (either pharmacologic or physiologic), therefore, tend to induce opposing changes in Pmc and Rv with respect to venous return. Vasodilatation decreases Pmc by decreasing stressed volume but also decreases Rv. Vasoconstriction results in increases of both Pmc and Rv. Only alterations in Vt alter Pmc without affecting Rv.

The venous return relationship is shown in **Figure 21.E3**.^{153,164,165} Because the systemic venous bed comprises the bulk of venous capacitance, the systemic venous vasculature dominates the physiology of venous return. Venous return is linearly related to Pa (right atrial pressure) down to 0 cm H₂O (= atmospheric pressure), at which point intermittent collapse of the great veins results in limitation of return producing the plateau.^{153,166} The slope of the line representing venous return is the inverse of the resistance (1/Rv). The ordinate intercept denotes the right atrial pressure (Pa) at which venous return is zero. But according to **Equation 1**, venous return is zero only when right atrial pressure (Pa) equals the Pmc. Thus, the intercept of the atrial pressure axis represents Pmc. Changes of Pmc shift the curve to the left or right without changing the slope of the line (see **Fig. 21.E3**, line a to line b and c). Changes of Rv change the slope of the line without changing the Pmc (see **Fig. 21.E3**, line a to line d and e).

Figure 21.E3 Graphic representation of venous return with varying atrial pressures, mean circulatory pressures, and venous resistance. Altering mean circulatory pressure displaces the line representing venous return (line a to line b or c) without changing the slope (which represents venous resistance to flow). Altering venous resistance changes the slope of the venous return curve (line a to line d or e) without changing the intercept point of the venous return line with the ordinate (which defines mean circulatory pressure). See text for details.

GRAPHIC ANALYSIS OF VENOUS-CARDIAC INTERACTIONS DURING SHOCK

In a closed system, cardiac output as determined by heart rate, preload, afterload, and contractility must equal venous return as determined by mean circulatory pressure, right atrial pressure, and venous resistance. Cardiac output, therefore, is not strictly a product of cardiac or vascular function but is dependent on their interaction. Because venous return and cardiac output are equal and are dependent on atrial pressure, the right heart Starling function curves can be superimposed on the systemic venous return curves using the same graphic parameters. The intersection of the two curves defines cardiac output and venous return for any given set of conditions involving the right heart and the systemic venous circulation. The circulatory physiology of shock can be described by the interaction of cardiac function and venous return curves.

Cardiogenic shock and obstructive shock due to increased afterload of the right or left ventricle (e.g., massive pulmonary embolus) result in a common change of the right ventricular Starling function curves. In the case of primary left ventricular loading or damage, this occurs because increased left ventricular filling pressures are passively transmitted to the right ventricle. The Starling curves are shifted downward and to the right (flatter) (**Fig. 21.E4**, point A to B), resulting in decreased cardiac output at increased atrial pressures. Therapy can consist of fluid resuscitation (increased Vt and Pmc), which may result in only modest augmentation of cardiac output despite significant increases of atrial pressures and ventricular filling pressures (point C); dobutamine, a beta-1 and beta-2 agonist that increases cardiac output by increasing contractility (point D); and both fluids and dobutamine (point E). Other catecholamines such as dopamine and norepinephrine, which both increase myocardial contractility and reduce venous capacitance, also increase afterload and have variable effects on cardiac output and venous return depending on which effect is dominant. Resistance to therapy may be noted if myocardial damage is sufficiently severe to flatten the Starling function curve to the point that increasing Pmc has

Figure 21.E4 Graphic representation of systemic venous return/right heart performance interactions during cardiogenic shock (point A to B) and therapy (see text for details).

Figure 21.E5 Graphic representation of systemic venous return/right heart performance interactions during hypovolemic shock (point A to B) and therapy (see text for details).

little effect on increasing venous return/cardiac output and insufficient functional myocardium remains to respond to inotropes with increased contractility (a steeper Starling relationship).

Hypovolemic shock results from decreased V_t , V_s , and P_{mc} (Fig. 21.E5, point A to B). The venous return curve is shifted downward and to the left, resulting in a reduced venous return and cardiac output at lower right atrial pressures. Although late depression of myocardial contractility with shift of the Starling function curve downward and to the right (analogous to myocardial depression during cardiogenic shock) has been noted in experimental hemorrhagic shock,^{35,36} this phenomenon is not considered here. Volume therapy, whether with crystalloid or colloid, tends to correct P_{mc} and venous return toward the original value (point C). Although optimal therapy of hypovolemic shock involves volume resuscitation, low-dose catecholamines exert similar hemodynamic effects; P_{mc} (and venous return) are augmented by an increase of the stressed volume (V_s), whereas the total (reduced from baseline) circulating volume (V_t) is unchanged (also point C).^{165,167,168} These changes outweigh any deleterious effect on increasing venous resistance (R_v). Cardiac contractility and vascular resistance are minimally affected at these doses. At moderate infusion rates (and with sympathetic stimulation), cardiac contractility is also augmented (point D). With higher catecholamine infusion rates, venous resistance and afterload may increase to the point of decreasing cardiac output and venous return (not shown). For that reason, vasopressors may be used only with great caution in hypovolemic shock.

Septic shock is especially complicated. Sepsis may involve elements of hypovolemia, myocardial depression, and altered distribution of cardiac output. Total circulating volume (V_t) and stressed volume (V_s) are decreased due to loss of fluids to the interstitium (third-spacing) and due to insensible losses. Stressed circulating volume (V_s) is further decreased due to active dilation of small venules/veins resulting in increased venous capacitance. This increase in unstressed volume (V_t) and decrease in stressed volume

Figure 21.E6 Graphic representation of systemic venous return/right heart performance interactions during septic shock (point A to B) and therapy (see text for details).

(V_s) have been confirmed in experimental animal models of canine and porcine endotoxemia.^{120,169} Thus, in unresuscitated septic shock, P_{mc} is almost universally decreased, resulting in reduced venous return and cardiac output (Fig. 21.E6, point A to B). Sepsis is also associated with dilatation of large veins and shunting of arterial blood flow to low-resistance (fast time constant) vascular beds, both of which decrease venous resistance and tend to augment venous return. Decreased venous resistance, however, does not fully compensate for decreased P_{mc} in unresuscitated septic shock. Cardiac output remains depressed (point B to C). With fluid resuscitation, P_{mc} may be corrected back toward normal, allowing the decreased R_v to be manifested by supernormal cardiac output and venous return (point D).¹²⁰ Patients with septic shock also develop myocardial depression, which is typically masked by the overall increase in cardiac output (point E). In about a fifth of patients, however, myocardial depression is sufficiently severe that venous return and, therefore, cardiac output remain depressed even after resuscitation (point F).

Human data suggest that sepsis is associated with a decrease of total vascular compliance.^{170,171} However, it is unclear whether this represents a primary septic phenomenon or a neurohumorally mediated compensatory response.^{170,172,173} Following fluid resuscitation, therapy of septic shock primarily involves catecholamines such as norepinephrine and dopamine. These affect the venous and cardiac function curves as specified earlier, although there are some data to suggest that both vascular and myocardial responsiveness to sympathomimetics may be reduced. In addition, they may also affect vascular compliance similar to

the potential compensatory neurohumoral effects described earlier.

Obstructive forms of shock such as those due to pericardial tamponade and tension pneumothorax can also be analyzed in the context of venous-cardiac interactions. For a detailed review of this subject matter, the reader is referred to several excellent reviews.^{158,174}

Ventricular function of each distinct form of shock can also be examined by using end-systolic and end-diastolic pressure-volume analysis. This analysis can be demonstrated graphically using ventricular pressure-volume loops. Changes in stroke volume and ventricular contractility can be examined with respect to ventricular volume and pressure alterations in circulatory shock states. Although this represents a useful approach to the study of circulatory shock physiology, a review of the subject is beyond the scope of this chapter. The interested reader is referred to a number of cogent reviews.¹⁷⁵⁻¹⁷⁷

MICROVASCULAR FUNCTION IN SHOCK

Preserved microvascular (vessels less than 100 to 150 μm in diameter) function is a critical determinant of appropriate tissue perfusion during shock. Although adequate cardiac output at sufficient blood pressure is required for appropriate global perfusion and systemic hemodynamics, effective tissue perfusion also requires intact local and systemic microvascular function.

Distribution of cardiac output is a complicated process involving local intrinsic autoregulation and extrinsic regulation mediated by autonomic tone and humoral factors. Blood flow to individual organs may be affected by system-wide changes in microarteriolar tone or by local alterations in metabolic activity. Blood flow within organs also requires microvascular regulation to match blood flow to areas of highest metabolic activity.

Intrinsic control (autoregulation) of blood flow is thought to occur through two mechanisms. Rapid alterations of

microvascular tone are mediated through endothelial stretch receptors so that sudden changes in perfusion pressure can be compensated by opposing changes in vascular resistance in order to maintain perfusion.¹⁷⁸ In addition, increases in metabolic activity within tissues and organs are thought to cause local elevation of various metabolites (CO_2 , H^+ , etc.), resulting in vasodilation and increased perfusion to match substrate demand.¹⁷⁸

Extrinsic control of vascular tone is primarily exerted through the autonomic nervous system. Parasympathetic release of acetylcholine to blood vessels results in nitric oxide and cyclic guanosine monophosphate (cGMP) generation in endothelial cells and vascular smooth muscle leading to vascular relaxation. Increases of sympathetic tone cause local norepinephrine release, activation of vascular α -adrenoreceptors, and increased vascular tone (Fig. 21.E7). Under stress, epinephrine and norepinephrine can be systemically released by sympathetic stimulation of the adrenal medulla. Basal control of blood pressure and flow resides in the activity of the renin-angiotensin system.

Alterations in microvascular function are effected through pre- and postcapillary sphincters that are sensitive to both intrinsic and extrinsic control mechanisms. Because the exchange of carbon dioxide, oxygen, and other substrates/metabolites as well as the compartmental regulation of fluids occurs at the capillary level, alteration of tone of either sphincter may have varying effects. Opening of either non-nutrient capillary sphincters (microanatomic shunts)⁸⁵ or increased flow to hypometabolic tissues (functional shunts)⁸⁶ will result in a suboptimal distribution of substrate supply with increased MVO_2 . Failure to dilate sphincters supplying metabolically active tissues may result in ischemia and anaerobic metabolism with lactate production. Increased precapillary tone as seen with sympathetic stimulation results in increased blood pressure systemically and decreased hydrostatic pressure locally. This decreased hydrostatic pressure favors redistribution of volume from the interstitium to the circulation. Increased postcapillary

tone (relative to precapillary) results in vascular pooling of blood and loss of fluid to the interstitium (due to increased hydrostatic pressure).

Organ blood flow changes are well characterized in shock states. Autoregulation of blood flow is dependent on maintenance of blood pressure within a defined range that varies among organs. The autoregulatory capacity of various organs can be determined by mechanically altering blood pressure in the organ vascular bed. With isolated local hypotension, the brain exhibits dominant autoregulatory capability with the ability to maintain blood flow over a wide range of pressures (30 to 200 mm Hg in dogs).¹⁵⁴ Coronary perfusion is also substantially autoregulated between 40 and 100 mm Hg. In contrast, mesenteric and renal blood flow becomes pressure dependent below about 60 mm Hg, whereas the vascular bed of skeletal muscle behaves in a passive manner at pressures outside 50 and 100 mm Hg. Human data suggest that overall, good autoregulation of blood flow exists in humans between pressures of 60 and 100 mm Hg.¹⁵⁴ In the context of normal physiology, blood flow is not effectively autoregulated outside this range. Without local adaptation, this would result in a mismatching of blood flow and metabolic demands producing organ failure and the metabolic correlates of shock. However, extrinsic adaptive mechanisms to protect the most vital organs come into play.

During hypovolemia and other hypodynamic forms of shock, extrinsic blood flow regulatory mechanisms overwhelm the autoregulatory response of most vascular beds. Blood flow to the heart and brain are well preserved due to dominant local autoregulation of flow. Blood flow to other organs is reduced relative to the decrease in total cardiac output as organ vascular resistance increases to maintain blood pressure.¹⁷⁹ This effect is mediated in part by both sympathetic neural activity and adrenal release of catecholamines.^{154,179} This adaptive mechanism maintains perfusion to vital organs at mild to moderate levels of reduced cardiac output. If the insult is sufficiently severe or prolonged, organ ischemia and subsequent organ failure may develop. Even if resuscitation restores systemic circulatory hemodynamics, microvascular perfusion abnormalities persist for days.¹⁸⁰ Experimental data suggest that perfusion of brain, kidneys, liver, and other splanchnic organs remains impaired following resuscitation from hemorrhagic shock.¹⁸⁰ Persistence of inadequate matching of tissue substrate demand and delivery after resuscitation of shock can lead to continued ischemia/hypoxia of some tissues. This may explain why hemorrhagic shock–related tissue injury can be irreversible if its duration and severity are excessive. Animal models suggest this irreversible phase of severe hemorrhagic shock is characterized by vasodilatation of precapillary sphincters.³⁷

During sepsis and septic shock, organ blood flow is disturbed at higher mean arterial pressures, suggesting a primary defect of microvascular function. Cerebral blood flow to the brain in humans has been shown to be depressed even before the onset of septic shock in patients with systemic inflammatory response syndrome.¹⁸¹ This pathologic vasoconstriction (apparently a unique response of the cerebral circulation to sepsis) does not appear to be the cause of septic encephalopathy. Cerebral autoregulation remains intact during sepsis.¹⁸² The greater decrease in coronary

than systemic vascular resistance during human septic shock may suggest that myocardial autoregulation also remains intact despite the fact that, in contrast to the brain, myocardial perfusion is often increased during septic shock.^{183,184}

Animal models demonstrate that all other vascular beds (splanchnic, renal, skeletal, cutaneous) exhibit decreased vascular resistance, with flow in these beds becoming increasingly dependent on cardiac output. This suggests both an active vasodilatory process and failure of extrinsic control of blood flow.¹⁵⁴ Inappropriate levels of splanchnic and skeletal muscle perfusion are also observed in humans during sepsis.⁸⁸ Other experimental data suggest that sepsis and septic shock are also associated with aberrant distribution of flow within organs.⁸⁶ In sepsis, vasodilatation and autoregulatory failure of the microvasculature may be responsible for mismatches of oxygen delivery and demand, resulting in anaerobic glycolysis with lactate production despite increased mixed venous oxygen saturation.

During both irreversible hemorrhagic shock and septic shock, peripheral vascular failure results in worsened matching of tissue demand and substrate supply, leading to failure of all organs and death. Among the potential responsible mechanisms are (1) tissue acidosis,¹⁸⁵ (2) catecholamine depletion and mediator-related vascular resistance to catecholamines,¹⁸⁶ (3) release of vasodilating and vasoconstricting arachidonic acid metabolites,¹⁸⁷ (4) decreased sympathetic tone due to altered central nervous system perfusion,¹⁸⁸ and (5) pathologic generation of nitric oxide by vascular smooth muscle cells.^{38,189}

In addition to vasomotor dysfunction, shock is associated with other microvascular pathology. Prime among these is disruption of endothelial cell barrier integrity. The endothelial layer is responsible for maintaining oncotic proteins (mostly albumin) within the circulatory space. During shock, capillary permeability increases, resulting in a loss of plasma proteins into the interstitium. Endothelial injury, through the action of neutrophil-generated free radicals¹⁹⁰ and nitric oxide/peroxynitrite generation,^{191,192} may account for this phenomenon. The release of vasoactive intermediaries such as histamine, bradykinin, PAF, leukotrienes, and TNF α appear to drive this pathologic process. Injury is initiated by leukocyte-endothelial cell interactions via adhesion molecules (integrins, selectins) that allow emigration of neutrophils to the tissues. Blockade of such activity or depletion of neutrophils attenuates tissue injury in animal models of shock.¹⁹³ With the loss of plasma proteins, the plasma oncotic pressure drops, interstitial edema develops, and circulating volume falls.

There is also evidence of intravascular hemagglutination of red cells, white cells, and platelets in almost all shock syndromes.^{86,194} This may be due to primary microvascular clotting leading to microthrombi. Alternately, clotting may occur as a consequence of primary endothelial damage due to circulating cytokines, free radicals produced by reperfusion and neutrophils, or complement activation. In any case, the result may be further endothelial cell injury, microvascular abnormalities, and inadequate distribution of perfusion within tissues. Decreased deformability of erythrocytes due to membrane free radical injury may also play a role in microcirculatory alterations in hemorrhagic and septic shock.¹⁹⁵

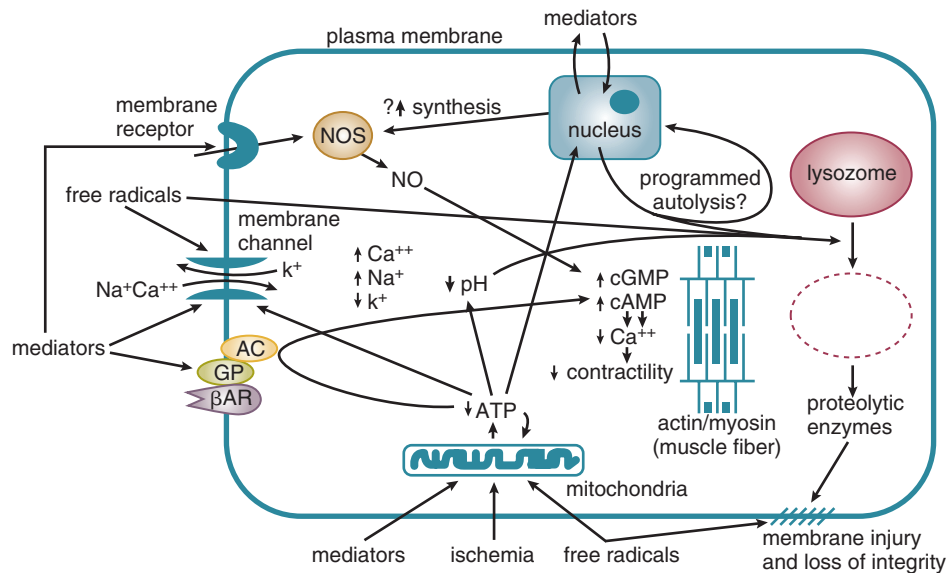

Figure 21.E8 Mechanisms of cellular dysfunction and injury in shock. Cell injury is mediated by multiple mechanisms during shock. Tissue ischemia may limit aerobic ATP generation. This results in further mitochondrial impairment due to deficits of mitochondrial membrane function, altered signal transduction including decreased muscle contractility (ATP is the precursor of cyclic AMP), impaired energy-dependent maintenance of transmembrane potential and ion gradients, increased intracellular pH due to anaerobic metabolism, and possible initiation of autolytic mechanisms. Free radicals may result in broad injury to cellular membranes resulting in impaired maintenance of transmembrane potential and ion gradients, mitochondrial generation of ATP, and activation of autolytic pathways involving DNA degradation and lysosomal rupture (apoptosis). Various circulating mediators (including cytokines, kinins, eicosanoids, and complement components) may result in mitochondrial dysfunction, signal transduction abnormalities, membrane protein channel alterations, and possibly alterations of gene expression. Any of these may lead to cell death through metabolic failure and lysosomal enzyme release. β AR, beta adrenergic receptor; GP, G proteins; NOS, nitric oxide synthetase; NO, nitric oxide; cGMP, cyclic GMP; cAMP, cyclic AMP.

MECHANISMS OF CELLULAR INJURY IN SHOCK

Although different forms of shock have their different precipitants, they do share common mechanisms of cellular dysfunction and injury. Eventually, events at the cellular level result in organ dysfunction and death. The pathogenesis of the cellular dysfunction is a combination of the inter-related precipitants and consequences of shock, including (1) ischemia, (2) inflammation, and (3) free radical injury (Fig. 21.E8). Genetic factors are also felt to play a role in an individual's susceptibility and response to shock.

The metabolic pathways involved in shock, like all cellular pathways, involve multiple levels of feedback. Some pathways will have positive feedback mechanisms, where an initial small signal will result in accelerating downstream effects, and negative feedback mechanisms, where downstream effects will result in down-regulation of upstream processes. Because cellular mechanisms from different signal transduction pathways often share common elements, different pathways will have positive and negative feedback effects on each other: this is termed *cross-talk*.

In all forms of shock, the hemodynamic changes involved eventually result in decreased oxygen delivery to target organs, with resultant cellular ischemia. The degree to which this is important in the development of organ damage and death in the different shock forms may vary, but it clearly is the major factor in hypodynamic forms of shock, and it also plays a large role in the ultimate mortality of hyperdynamic, hypermetabolic shock.

In the stressed preshock phase, physiologic adaptive mechanisms attempt to compensate, and perfusion to vital

Figure 21.E9 Aerobic and anaerobic glucose metabolism. Under anaerobic conditions, pyruvic acid cannot enter the citric acid cycle in the mitochondria (in order to optimally produce ATP) and is shunted to lactate in the cytoplasm. This produces fewer high-energy phosphates per mole of glucose metabolized. Hydrolysis of ATP molecules in an anaerobic environment results in production of H^+ ions, which cannot be metabolized or cleared, resulting in intracellular acidosis. (Adapted with permission from Mizock BA, Falk JL: Lactic acidosis in critical illness. Crit Care Med 1992;20:80.)

organs is maintained. With the onset of shock, these mechanisms fail, and thus oxygen delivery to tissues is not maintained. At the cellular level, a lack of oxygen prevents the mitochondrial citric acid cycle from functioning, and pyruvate accumulates (Fig. 21.E9). The failure of aerobic respiration requires shunting of pyruvate into the lactic acid pathway in order to recycle NAD and allow glycolysis to continue. However, the loss of the aerobic citric acid cycle results in a large decrease in adenosine triphosphate (ATP) production (net 2 molecules of ATP per molecule of glucose,

versus a theoretical net of 38 molecules of ATP per glucose molecule in the entire aerobic pathway). In addition, shunting to the lactic acid pathway results in the accumulation of hydrogen ions. Thus, loss of perfusion results in a rapid decrease in cellular energy stores, with inadequate ATP regeneration rates. As ATP is the primary source of energy in the cell, energy-dependent cellular systems cease functioning. This includes energy-dependent enzymes, maintenance of transmembrane gradients including electrical potential,¹⁹⁶ mitochondrial function,¹⁹⁷ carbohydrate metabolism,¹⁹⁸ and even the glycolysis pathway itself, which requires two ATP molecules to prime each glucose molecule at the entry point into the pathway. Some cell types are more sensitive than others to the depletion of energy stores, such as in the liver and kidney, but eventually all organs are affected.^{196,199-202} With the loss of energy-dependent cell maintenance functions, ultrastructural breakdown, including mitochondria, occurs.²⁰³ Systemically, the combination of worsening acidosis and loss of energy stores results in a positive feedback loop of worsening shock, organ failure, and eventual death.

Ischemia is felt to play a minor role in early sepsis, with high cardiac outputs maintaining perfusion to more sensitive, higher energy-consuming tissues, and that ATP levels remain normal in these tissues, with mitochondrial function preserved. Instead, early septic organ dysfunction results from other causes.^{101,102,105} However, localized areas of ischemia are not ruled out. Potentially, microthrombi may result in small areas of decreased microcirculatory flow, resulting in localized ischemia. Evidence to support a role for ischemia in cellular dysfunction in sepsis includes oxygen-supply-dependent oxygen consumption, washout of organic acids from ischemic areas in patients in septic shock on vasodilators, and elevated ATP degradation products. In any case, the role of ischemia in septic shock remains a question. For example, alterations of liver and skeletal muscle transmembrane potential occur early in shock prior to the decrease in levels of high-energy phosphates and onset of hypotension. Further, this membrane defect is not prevented by the administration of membrane-permeable forms of high-energy phosphates such as ATP-MgCl₂.²⁰⁴

Inflammation, on the other hand, is a major contributor to the development of septic shock and its effects on cellular and organ dysfunction.^{205,206} Other forms of shock also activate the inflammatory cascade—for example, hemorrhagic shock with tissue trauma.²⁰⁷ Indeed, shock is associated with systemic activation of the inflammatory cascade. The resulting cellular and tissue dysfunction, and thus hypermetabolic state, contributes to organ dysfunction and failure. The inflammatory cascade in sepsis can be roughly broken down into initiation, transduction, and release of inflammatory mediators.

Initiation of the inflammatory cascade in sepsis is thought to rely largely on the innate immune response.^{206,208,209} This ancient immune pathway evolved to recognize non-self molecular signatures, produced by pathogens including bacteria, yeast, and viruses, which have remained invariant over time. These signatures are called pathogen-associated molecular patterns (PAMPs), and they are recognized by a series of receptors known as pattern recognition receptors (PRRs). In addition, signature host proteins can also be released extracellularly in response to cellular damage, and

these proteins, also called alarmins, are known as damage-associated molecular patterns (DAMPs), and these too may be recognized by PRRs. Thus, both non-self PAMPs and self-expressed DAMPs may lead to initiation of the inflammatory cascade via the PRRs.

Known PRRs include (1) the Toll-like receptors (TLRs), (2) the C-type lectin receptors (CLRs), (3) the nucleotide oligomerization domain (NOD)-like receptors (NLRs), and (4) retinoic acid inducible gene I-like receptors (RLRs).

The TLRs and CLRs, being transmembrane, are presented on the cell surface or within the lumens of endosomes or lysosomes.^{206,210,211} Ten families of TLRs have been identified in humans. Different TLR families on the cell surface recognize various bacterial lipoproteins, lipopolysaccharides, or flagellins, with sources that may be bacterial, viral, or protozoan. In contrast, TLR families located in endosomal lumens recognize ssRNA, dsRNA, and modified CpG-DNA, which may be of viral or bacterial origin. Interestingly, different individual families of TLRs can form both homodimers and heterodimers on the cell surface, increasing their range of ligand recognition. Meanwhile, the CLRs are presented on the cell surface, and being lectins, they recognize polysaccharides present in yeast and fungi, mycobacteria, and viruses.

In contrast, the NLRs and RLRs are intracellular and require that their ligands be present in the cytoplasm of the cell.²¹¹ NLRs recognize bacterial peptidoglycans; the RLR ligands consist primarily of dsRNA, cytoplasmically produced either by dsRNA viruses or as an intermediate step in the replication of ssRNA viruses.

Once initiated by recognition of PAMPs or DAMPs, the inflammatory cascade involves a large number of protein, kinase, and second messenger cascades. These cascades can lead to the activation of transcription factors or to the post-transcriptional or posttranslational activation of inflammatory mediators.

The TLRs have been shown to use two primary pathways.²¹¹ All the TLRs, with the exception of TLR3, use a pathway dependent on the adaptor protein MyD88, which binds to the intracellular sections of the TLRs; for some of the TLRs, another adaptor protein is required to bind MyD88. Upon activation of the TLR, MyD88 recruits a serine/threonine kinase, IRAK-4, in turn recruiting further kinases such as IRAK-1 and IRAK-2. Ultimately, the cytoplasmic cascade results in phosphorylation and degradation of I κ B, an inhibitor of the transcription factor NF- κ B. This allows NF- κ B to enter the nucleus, resulting in the activation of transcription of a suite of inflammatory mediators and modulators. In contrast, TLR3 uses a pathway dependent on the TRIF adaptor protein, which also ultimately results in NF- κ B activation. In both pathways, other adaptor proteins may be required for individual TLRs to activate these cascades; for example, TLR4 can also utilize the TRIF-dependent pathway but is dependent on the TRAM adaptor protein to do this. Different cell types may express different adaptor proteins, resulting in intertissue variation in the cascades. In addition, protein inhibitors of the cascades can be expressed variably in different cell types.

In contrast, the NLRs act via formation of a multiprotein complex, termed the *inflammasome*.^{206,211,212} Central to this cascade are the caspases,²¹³ a family of cysteine proteases. Upon activation, the NLR will recruit a pro-caspase, along

with an adaptor protein ASC, which recruits a second procaspase. This complex allows the procaspase pair to auto-activate, resulting in active caspase. The best studied of these is caspase 1, although other caspases may be involved. Once activated, caspase 1 in turn activates the inflammatory cytokine IL-1 β , allowing its release from the cell. Similarly, caspase 1 is also responsible for the activation and release of other cytokines, including IL-18. In this way, the NLR's prime function is to regulate inflammatory mediator release through a posttranslation system. Crosstalk from the TLR cascades may also activate some NLRs and result in inflammasome formation.

At the center of these cascades is transcriptional regulation of inflammatory cytokines and mediators. The transcription factor NF- κ B sits at the end of many of these cascades and plays a crucial role in the regulation of expression of many of these factors.^{206,211,214} NF- κ B is present in an inactive form in the cytoplasm, in complex with repressor proteins.²¹⁵ When the repressors, known as I κ B proteins, are phosphorylated and subsequently degraded, NF- κ B is released and transported into the nucleus where it can act on its target sequences. By being stored in inactive form in the cytoplasm, no new NF- κ B need be expressed, allowing for rapid response to the signals received by the PRRs. Inflammatory mediators under the control of NF- κ B include cytokines such as TNF α , IL-1 β and IL-6, enzymes involved in inflammation such as iNOS, and others.²⁰⁶

Inflammatory mediator effects on cellular metabolism are of prime importance in organ dysfunction due to sepsis and septic shock. Circulating inflammatory mediators may also play a substantial role in other forms of shock, including hemorrhagic shock associated with extensive tissue trauma.^{216,217} Both sepsis and trauma are associated with generalized, systemic activation of the inflammatory response. Resulting cell injury and hypermetabolism may culminate in organ failure. A number of triggers can result in activation of the inflammatory cascade. The best studied is endotoxin from gram-negative bacteria, but other bacterial antigens and cell injury itself can also initiate the cascade. Macrophage production of cytokines such as TNF α , IL-1 β , and IL-6 appears to be central.

Tumor necrosis factor- α (TNF α) is a 51-kD trimeric peptide produced by macrophages in response to a variety of inflammatory stimuli including bacterial antigens and other cytokines. Circulating levels of TNF α are transiently elevated soon after the onset of shock (particularly septic shock).²¹⁸ Administration of TNF α to animals or humans results in a hyperdynamic circulatory state (\pm dose-dependent hypotension) similar to untreated sepsis and septic shock.¹²⁶ Although clinical trials to date have yielded disappointing results, anti-TNF α strategies protect animals from experimental endotoxic and septic shock.²¹⁹ Among the many effects of TNF α are the release of IL-1 β , IL-6, IL-8, PAF, leukotrienes, thromboxanes, and prostaglandins; stimulation of production and activity of polymorphonuclear leukocytes; promotion of immune cell adhesion to endothelium; activation of coagulation and complement systems; direct endothelial cell cytotoxicity; depression of myocardial contractility; and fever production by the hypothalamus.^{126,220} Notably, TNF α causes alterations of skeletal transmembrane electrical potential similar to those described in hemorrhagic and septic shock.²²¹ These membrane effects precede

hemodynamic alterations, suggesting that TNF α exerts a primary effect on cell metabolism independent of perfusion alterations. Although TNF α appears to be of central importance in the pathogenesis of septic shock, it is also known to be elevated in congestive heart failure²²² and hemorrhagic shock.²¹⁶

Other substances involved in the inflammatory process include IL-1 β , which can potentiate the *in vivo* effects of TNF α ; IL-2, which can cause hemodynamic abnormalities in humans; IL-6, which is involved in the acute phase response and has been implicated in septic myocardial depression; interferon- γ , which promotes the release of other cytokines, enhances adhesion of immune cells, and promotes macrophage activation; IL-10, which is an anti-inflammatory cytokine that limits macrophage generation of pro-inflammatory cytokines; TGF β , which is another anti-inflammatory cytokine that, in addition to limiting macrophage pro-inflammatory responses, also blocks the effects of proinflammatory cytokines on target cells; endothelin-1, a cytokine that strongly promotes vasoconstriction, particularly in the renal vascular bed, possibly resulting in renal hypoperfusion and decreased glomerular filtration rate; PAF, which stimulates TNF α , thromboxane, and leukotriene release, stimulates free radical formation, and alters microvascular permeability; leukotrienes, which release other arachidonic acid metabolites, alter vascular endothelial permeability, and may mediate vascular and myocardial depression in shock; thromboxanes, which may contribute to altered microvascular vasomotor and permeability function; prostaglandins, which produce fever, induce vasodilatation, and inhibit thrombus formation; and complement fragments C3a and C5a, which constrict vascular smooth muscle, release histamine, and promote chemotaxis.^{130,220,223}

Several newly recognized mediators/mediator groups have been shown to have important roles in shock, particularly septic shock. These include high-mobility group 1 protein (HMG-1), myocardial depressant substances and nitric oxide/peroxynitrites. HMG-1 appears to have a key role in the late pathogenesis of sepsis^{224,225} and may also have a role in traumatic/hemorrhagic shock.²²⁶⁻²²⁸ HMG-1 is a late mediator of inflammation. Mice show increased levels of HMG-1 in serum 8 to 32 hours after endotoxin administration. Patients succumbing to septic shock also demonstrate increased serum HMG-1 levels.²²⁴ Administration of HMG-1 to normal and endotoxin-resistant mice induces dose-dependent mortality with signs consistent with endotoxic shock.^{224,225} Several anti-HMG-1 therapies are in development.²²⁸

A circulating myocardial depressant substance is present in the blood of patients with septic shock who exhibit myocardial depression with biventricular dilatation and reduced ventricular ejection fractions.²²⁹ Similar substances have been shown to be present in animal models of hemorrhagic shock.²³⁰ Other data suggest canine myocardial infarction²³¹ and human cardiogenic shock²³² may also be associated with circulating myocardial depressant substances. Serum from appropriate septic patients or animal models depresses myocardial tissue *in vitro*.^{32,229} Myocardial depressant substances from both septic and hemorrhagic shock appear to be dependent on calcium.²³³ The substance implicated in human sepsis may represent a synergistic combination of TNF α and IL-1 β that produces depression by inducing

myocardial nitric oxide production.^{229,234,235} $\text{TNF}\alpha$ and $\text{IL-1}\beta$ are both elevated in shock and cause similar depression of myocardial tissue.^{234,236} Other data suggest that IL-6 may have a central role.^{130,223,237}

Another important mediator, nitric oxide (NO), has a vital role in normal intracellular signal transduction.²³⁸ Of particular importance to shock, NO is the mediator through which endothelial cells normally cause relaxation of adjacent smooth muscle.²³⁸ Endothelial cells, through a constitutive nitric oxide synthetase, produce picomolar quantities of nitric oxide in response to a number of vasodilatory mediators such as acetylcholine and bradykinin. This NO diffuses to adjacent smooth muscle and activates guanylate cyclase to produce cyclic GMP, which affects vascular relaxation. Nitrovasodilators bypass nitric oxide synthetase to relax smooth muscle directly through the guanylate cyclase pathway. During septic shock, an inducible NO synthetase capable of producing nanomolar quantities of NO is generated in vascular smooth muscle.^{189,238} Studies have also implicated NO in late vascular dysfunction seen in hemorrhagic shock.³⁸ Nitric oxide-mediated generation of cyclic GMP may explain the profound loss of arterial vascular tone and venodilatation seen in septic shock^{189,239} and may, in part, explain the irreversible vascular collapse seen late in hemorrhagic shock.³⁸ A potential role for NO in inflammation-associated edema and third-spacing during shock has also been suggested.¹⁹¹ The *in vitro* myocardial depressant effects of $\text{TNF}\alpha$, $\text{IL-1}\beta$, and serum from septic humans may be mediated by a similar NO- and cyclic GMP-dependent pathway.^{126,234}

An alternative pathway by which NO may play a role in the cardiovascular pathophysiology of shock and sepsis was described by Beckman and colleagues in 1990.²⁴⁰ Peroxynitrite (ONOO-), a highly reactive oxidant, is produced from the interaction of superoxide (OH-) and nitric oxide (NO-). It is known to react rapidly with proteins, lipids, and DNA during sepsis and shock states.²⁴¹⁻²⁴⁴ Lipids may be peroxidized, and although proteins may be oxidized, nitrated, or nitrosated, the latter result in nitrotyrosine residues.^{240,245,246} Peroxynitrite inactivates mitochondrial aconitase disrupting the Krebs cycle and otherwise interferes with ATP production and utilization,²⁴⁷⁻²⁵² an activity similar to that described for NO.²⁵³⁻²⁵⁵ It also generates DNA strand breaks leading to poly-ADP ribose synthetase (PARS) activation that may itself have significant pathophysiologic effects.^{256,257} Peroxynitrite, like NO, also activates guanylate cyclase in vascular tissues.^{258,259} In the periphery, the result may be cellular energetic failure, vascular contractile dysfunction (vasodilation), and reperfusion injury.^{256,260-262} Many other molecular targets of NO relevant to the cardiovascular system exist and are well reviewed elsewhere.^{245,263}

It is of note that as part of the release of inflammatory mediators, immune cells including macrophages, polymorphonuclear leukocytes, and lymphocytes may also be activated in some forms of hypodynamic shock (e.g., hemorrhagic shock), resulting in a self-perpetuating, systemic inflammatory response (similar to that seen in sepsis). This response can contribute to vascular and parenchymal injury and culminate in MODS.

Free radical injury induced by reperfusion or neutrophil activity is another mechanism of organ injury during hemorrhagic and septic shock as well as burns and myocardial

infarction.²⁶⁴ During tissue ischemia, oxygen deficiency leads to accumulation of ATP degradation products including adenosine, inosine, and hypoxanthine (Fig. 21.E10).²⁶⁵ With resuscitation and reperfusion of ischemic areas, oxygen drives the generation of superoxide (O_2^-), the most common precursor of reactive oxidants, by xanthine oxidase, in endothelial cells. Most of the superoxide is converted, either spontaneously or through superoxide dismutase, to hydrogen peroxide (H_2O_2). This further reacts to produce tissue-damaging hydroxyl radicals (or other highly reactive free radicals).²⁶⁴ These radicals interact with critical cell targets such as the plasma membrane, lipid membranes of organelles, and various enzymes, resulting in cell lysis and tissue injury. Oxidant activity, directly and through endothelial damage, attracts and activates neutrophils, resulting in amplification of superoxide generation by a neutrophil NADPH-oxidase and in further tissue damage due to neutrophil protease release.²⁶⁴ Injured tissue may release xanthine oxidase into the circulation, resulting in systemic microvascular injury.²⁶⁶

A parallel process is found during reperfusion of ischemic myocardium following myocardial infarction.²⁶⁷ Thrombolytic therapy or balloon angioplasty results in sudden delivery of oxygen to ischemic myocardium. Although substantial salvage of myocardial function results, free oxygen radical-mediated reperfusion injury can contribute to myocardial “stunning.”²⁶⁸ Cardiogenic shock during this phase may resolve as the reperfusion injury settles. Free radical damage likely also plays a role in tissue damage during sepsis and septic shock. Following activation by inflammatory mediators and during phagocytosis, polymorphonuclear leukocytes undergo a respiratory burst during which they consume oxygen and generate both superoxide and hydrogen peroxide through a membrane-associated NADPH-oxidase.²⁶⁴ Macrophages similarly produce oxygen radicals upon activation. Activation also enhances adhesion and tissue migration of leukocytes so that both vascular endothelial and parenchymal tissue damage may result. Free radical injury may play an important role in the development of organ failure following shock.²⁶⁹

Variations in stress response genes between individuals and alteration of gene expression in immune, endothelial, muscle, and organ parenchymal cells are other important aspects of cellular dysfunction/injury in circulatory shock. Although shock can be present immediately after injury (massive trauma, hemorrhage, or endotoxin infusion) prior to the onset of substantial alterations of gene expression, its evolution is dependent on a combination of the ongoing nature of the insult, the genetically passive compensatory physiologic/metabolic response, the underlying genotype with respect to stress response elements, and stress-related modulation of gene expression in a variety of cells.

The clinical presentation of shock, progression of the syndrome, and final outcome may be substantially controlled by genetic factors.²⁷⁰ Genetic factors have been best studied in septic shock. Studies have demonstrated that the human $\text{TNF}\alpha$ promoter polymorphism, TNF2 , imparts an increased susceptibility to and mortality from septic shock.²⁷¹ Other studies suggest increased $\text{TNF}\alpha$ generation, severity of sepsis, and mortality with another human $\text{TNF}\alpha$ gene polymorphism.²⁷² A specific locus on chromosome 12 in mice has been shown to be associated with resistance to

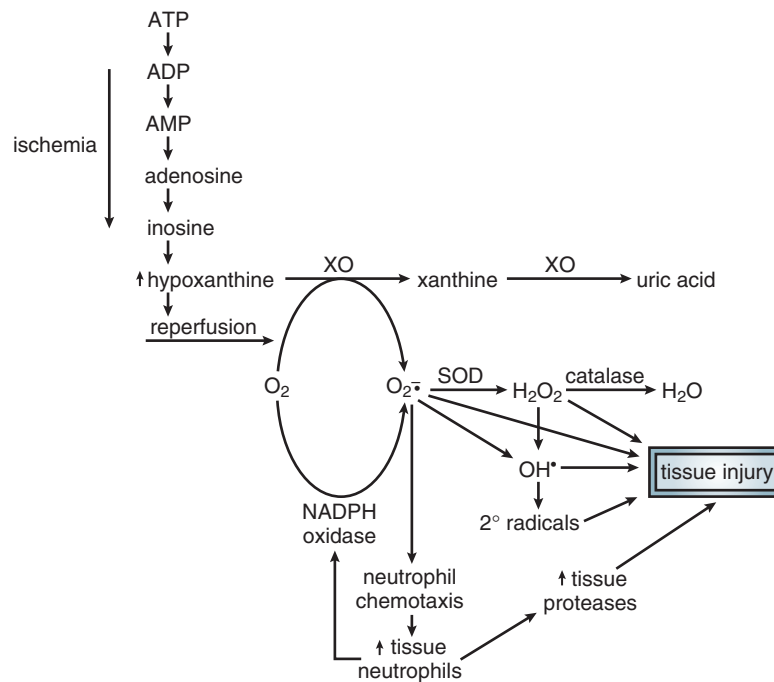

Figure 21.E10 Free radical-mediated tissue injury. Superoxide (O_2^-) is primarily produced in shock from hypoxanthine (a metabolite of ATP degradation) by xanthine oxidase (XO) during reperfusion post ischemia. Superoxide can be converted to hydrogen peroxide (H_2O_2) by superoxide dismutase (SOD) and then to H_2O or may be converted to the highly reactive hydroxyl (OH^\bullet), which mediates tissue injury. Free radical tissue injury may be amplified by superoxide recruitment of neutrophils, which secondarily produce additional superoxide through NADPH oxidase. (Adapted with permission from Calandra T, Baumgartner J, Grau GE, et al: Prognostic values of tumor necrosis factor/cachectin, interleukin-1, and interferon- γ in the serum of patients with septic shock. *J Infect Dis* 1990;161:982-987.)

mortality due to $TNF\alpha$ -induced shock.²⁷³ A human $IL-1\beta$ receptor antagonist gene polymorphism has been linked to increased susceptibility to sepsis.²⁷⁴ Several additional linked polymorphisms have been described.²⁷⁵ It appears likely that gene polymorphisms may play similar roles in other forms of shock.

Beyond the role of gene alleles in the development and clinical response to shock, the progression of irreversible circulatory shock and MODS may have its basis in genetically driven vascular or parenchymal responses. Production of cytokines by macrophages during shock requires acute expression of the genes coding for $TNF\alpha$, $IL-1\beta$, and other proinflammatory cytokines. The production of adhesion molecules by endothelial cells and inducible nitric oxide synthetase by vascular smooth muscle during shock requires active up-regulation of gene expression. Both events are

thought to be key to the development of MODS following shock in humans. In addition, human and animal research indicates that apoptosis, a genetically programmed process of cell autolysis, occurs in a variety of organs during shock and subsequent organ failure.^{276,277} Data suggest that a variety of transcription factors may be activated in models of sepsis in association with the process.²⁷⁸ Further research should elucidate the important link between irreversible/refractory shock/shock-associated MODS and genetically programmed cell responses to inflammatory stimulation or injury.

Whatever the initiating event or events, progressive cell metabolic failure occurs. Mitochondrial activity continues to deteriorate, subcellular organelles are damaged, and the intracellular (and possibly, systemic) release of lysosome hydrolytic enzymes occurs, accelerating cell death and organ failure.

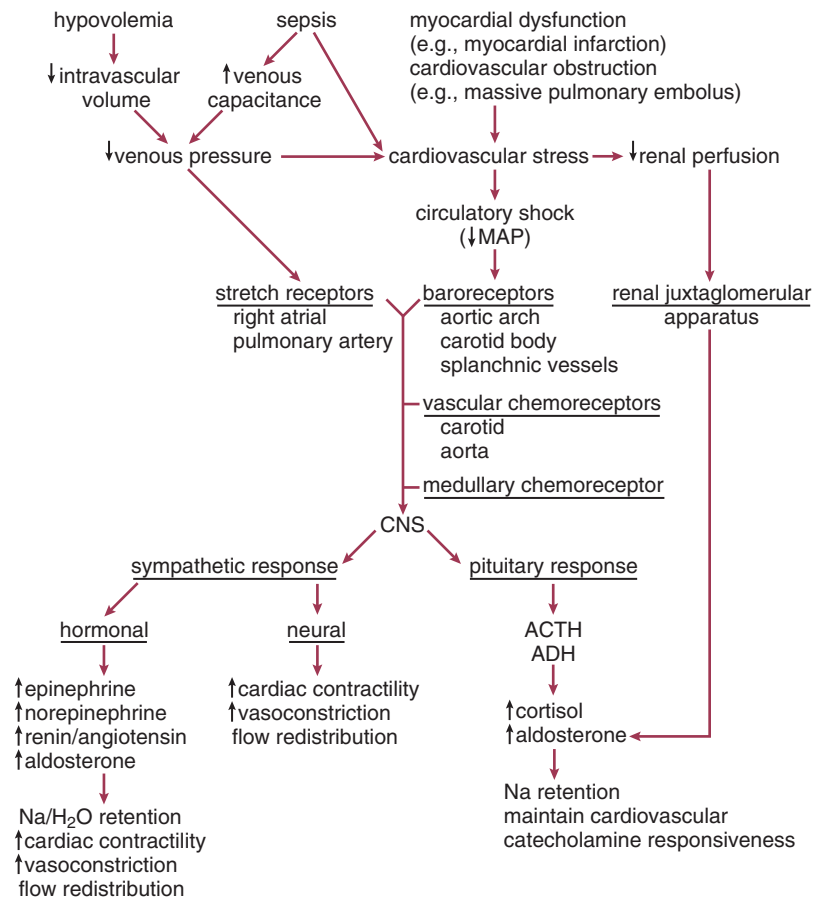

Figure 21.2 Neurohormonal response to shock. During early cardiovascular stress, the neurohormonal response may be limited to increased activity of the juxtaglomerular apparatus and stimulation of right atrial and pulmonary artery low-pressure mechanoreceptors. With further hypotension, high-pressure vascular baroreceptors, vascular chemoreceptors, and the medullary chemoreceptor are sequentially stimulated, resulting in augmented neurohormonal activity with increased pituitary hormone (ACTH and ADH) release and increased sympathetic outflow from the central nervous system. Volume retention, increased venous tone, increased cardiac contractility, and blood flow redistribution to vital organs results.

constriction results in a fall in glomerular filtration rate and urine output. In addition, decreased renal perfusion pressure, sympathetic stimulation, and compositional changes in tubular fluid¹⁵³ result in renin release from the juxtaglomerular apparatus. Renin release leads to the adrenal cortical release of aldosterone (via angiotensin II), which increases sodium reabsorption in the distal tubules of the kidney in exchange for potassium or hydrogen ion.¹⁵³ Angiotensin II also exerts a powerful direct vasoconstricting effect (particularly on mesenteric vessels) while increasing sympathetic outflow and adrenal epinephrine release. As noted, vasopressin (antidiuretic hormone) release occurs through activation of right atrial low pressure. Angiotensin II augments this release by increasing sympathetic outflow. The release of vasopressin from the posterior pituitary results in water retention at the expense of osmolality. Hyponatremia can result. Vasopressin, like angiotensin II, also results in vasoconstriction, particularly of the splanchnic circulation.

Finally, increased sympathetic activity and release of adrenal epinephrine results in systemic venoconstriction, particularly of the venous capacitance vessels of the splanchnic circulation. This supports mean circulatory pressure and venous return by increasing stressed volume.

Increased sympathetic nervous system activity accounts for most of the enhancement of cardiac performance during

shock. Local release of norepinephrine by sympathetic nerves and the systemic release of epinephrine result in the stimulation of cardiac alpha and beta-adrenergic receptors resulting in increases of heart rate and contractility that optimize cardiac output and support blood pressure. Angiotensin II may also exert direct as well as indirect (sympathetic stimulation) inotropic effects on myocardium. Improved cardiac function also results in decreased right atrial pressure, which tends to increase venous return.

Redistribution of blood flow during shock has already been discussed. Increased sympathetic vasoconstrictor tone, systemic release of epinephrine from the adrenals, vasopressin, endothelin, and angiotensin II cause vasoconstriction in all sensitive vascular beds including the skin, skeletal muscle, kidneys, and splanchnic organs.¹⁵⁴ Dominant autoregulatory control of blood flow spares brain and heart blood work from these effects. Redistribution of flow to these vital organs is the effective result.

The effects of decreased delivery of oxygen to the tissues during shock can be attenuated by local adaptive responses. Hypoperfusion and tissue ischemia will result in local acidosis due to decreased clearance of CO₂ and anaerobic metabolism. Local acidosis decreases the affinity between oxygen and hemoglobin at the capillary level.¹⁵³ The resultant rightward shift of the oxyhemoglobin dissociation curve allows

Metabolic	Hyperglycemia Glycogenolysis Gluconeogenesis Hypoglycemia (late) Hypertriglyceridemia
Immune System	Gut barrier function depression Cellular immune depression Humoral immune depression

greater unloading of oxygen from hemoglobin for a given P_{O_2} . Tissue ischemia is also accompanied by decreased tissue P_{O_2} (relative to normal), which further augments the unloading of oxygen. Pyrexia associated with sepsis may also contribute to a rightward shift of the oxyhemoglobin dissociation curve, whereas hypothermia is associated with a leftward shift. For that reason, maintenance of normothermia during resuscitation from shock helps to optimize oxygen unloading.

ORGAN SYSTEM DYSFUNCTION DUE TO SHOCK (TABLE 21.3)

CENTRAL NERVOUS SYSTEM

Central nervous system neurons are extremely sensitive to ischemia. Fortunately, the central nervous system vascular supply is highly resistant to extrinsic regulatory mechanisms. Although cerebral perfusion is clearly impaired in shock, flow remains relatively well preserved until the later stages.^{284,285} Absent primary cerebrovascular impairment, cerebral function is well supported until mean arterial pressure falls below approximately 50 to 60 mm Hg.²⁸⁶ Eventually, irreversible ischemic injury may occur to the most sensitive areas of the brain (cerebral cortex). Before this

fixed injury, an altered level of consciousness, varying from confusion to unconsciousness, may be seen depending on the degree of perfusion deficit. Disturbances of acid/base/electrolytes may also contribute. Electroencephalographic (EEG) recordings demonstrate nonspecific changes compatible with encephalopathy. Sepsis-related encephalopathy may occur at higher blood pressures (due in part to the effects of circulating inflammatory mediators) and is associated with increased mortality.²⁸⁷

HEART

The major clinically apparent manifestations of shock on the heart are due to sympathoadrenal stimulation. Increased heart rate, in the absence of disturbances of cardiac conduction, is almost universally present. Vagally mediated paradoxical bradycardia may be seen on occasion in severe hemorrhage.⁴⁰ In patients predisposed to myocardial ischemia or irritability, catecholamine-driven supraventricular tachycardias and ventricular ectopy with ischemic electrocardiogram (ECG) changes are not common. Like the brain, the blood supply to the heart is autoregulated. This, in combination with the resilient nature of myocardial tissue, renders it resistant to sympathetically driven

vasoconstriction and shock-related hypoperfusion injury. Overt necrosis does not typically occur, although evidence of cellular injury may be present.

Most forms of shock are associated with increased contractility of healthy myocardium. Regardless, shock can have a substantial impact on myocardial contractility and compliance. Hypotension during cardiogenic (and other forms of shock) is associated with decreased coronary artery perfusion pressure. In patients with coronary artery disease or increased filling pressures, decreased coronary artery perfusion pressure may lead to overt ischemia. Further, circulating myocardial depressant substances contribute to myocardial depression in septic²²⁹ and hemorrhagic²³⁰ shock. This has been linked to decreased beta adrenoreceptor affinity and density as well as potential defects of intracellular signal transduction involving nitric oxide, G proteins, cAMP, and cGMP.¹²⁶ Circulating depressant substances may also be present during cardiogenic shock.²³²

RESPIRATORY SYSTEM

Early alterations of pulmonary function seen during acute circulatory shock are primarily related to changes in central drive or muscle fatigue. Increased minute volume occurs as a result of augmented respiratory drive due to peripheral stimulation of pulmonary J receptors and carotid body chemoreceptors as well as hypoperfusion of the medullary respiratory center. This results in hypocapnia and primary respiratory alkalosis.^{153,288} With increased minute volume and decreased cardiac output, the V/Q ratio increases. Unless arterial hypoxemia complicates shock, pulmonary resistance is initially unchanged or minimally increased. Coupled with an increased workload, respiratory and diaphragmatic muscle impairment due to hypoperfusion (manifested by decreased transmembrane electrical potential) may lead to early respiratory failure.²⁸⁹ Adult respiratory distress syndrome (ARDS) due to inflammatory or free radical injury to the alveolar capillary cell layers following established shock may develop as a late cause of respiratory failure.

KIDNEY

Acute renal failure is a major complication of circulatory shock with associated mortality rates between 35% and 80%.²⁹⁰ Although initial injury manifested by decreased urine output occurs, other clinical manifestations of renal dysfunction (increased creatinine, urea, and potassium) may not be noted for 1 to 3 days. Once hemodynamic stabilization has been achieved, it becomes apparent that urine output does not immediately improve and both serum creatinine and urea continue to rise. The single most common cause of acute renal failure is renal hypoperfusion resulting in acute tubular necrosis (ATN). The most frequent cause of renal hypoperfusion is hemodynamic compromise from septic shock, hemorrhage, hypovolemia, trauma, and major operative procedures. ATN that occurs in the setting of circulatory shock is associated with a higher mortality than in other situations.

Part of the reason for the kidney's sensitivity to hypoperfusion has to do with the nature of its vascular supply. The renal vascular bed is moderately autoregulated. Increases of efferent arteriolar tone can initially maintain glomerular perfusion despite compromise of renal flow.²⁹¹ Renal

hypoperfusion does not become critical until relatively late in shock when maximal vasoconstriction of renal preglomerular arterioles²⁹¹ results in cortical, then medullary, ischemic injury.

Decreased urine output in shock can pose a diagnostic dilemma, as it can be associated with both oliguric ATN and hypoperfusion-related prerenal failure without ATN. Indices suggestive of the latter include a benign urine sediment, a urine sodium concentration <20 mEq/L, fractional urine sodium excretion <1%, urine osmolality >450 mOsm/L, and a urine/plasma creatinine ratio >40. Useful markers of acute renal failure due to ATN include hematuria and heme granular casts, a urine sodium concentration >40 mEq/mL, fractional excretion of urine sodium to >2%, urine osmolality <350 mOsm/L, and a urine:plasma creatinine ratio <20.²⁹² Of note, ATN caused by circulatory shock may be associated with urine sodium <20 mEq/L and fractional excretion <1% if the acute renal injury is superimposed upon chronic effective volume depletion as may be seen with cirrhosis and congestive heart failure.²⁹³

GASTROINTESTINAL SYSTEM

The gut is relatively sensitive to circulatory failure. The splanchnic vasculature is highly responsive to sympathetic vasoconstriction. Typical clinical gut manifestations of hypoperfusion, sympathetic stimulation, and inflammatory injury associated with shock include ileus, erosive gastritis, pancreatitis, acalculous cholecystitis, and colonic submucosal hemorrhage. Enteric ischemia produced by circulatory shock and free radical injury with resuscitation may breach gut barrier integrity with translocation of enteric bacteria and antigens (notably endotoxin) from the gut lumen to the systemic circulation, resulting in the propagation and amplification of shock and MODS.^{294,295}

LIVER

Like the gut, the liver is highly sensitive to hypotension and hypoperfusion injury. "Shock liver," associated with massive ischemic necrosis and major elevations of transaminases, is atypical in the absence of extensive hepatocellular disease on very severe insult.²⁹⁶ Centrilobular injury with mild increases of transaminases and lactate dehydrogenase is more typical. Transaminases usually peak within 1 to 3 days of the insult and resolve over 3 to 10 days. In either case, early increases in bilirubin and alkaline phosphatase are modest. Despite the production of acute phase reactants in early circulatory shock, synthetic functions may be impaired with decreased generation of prealbumin, albumin, and hepatic coagulation factors. After hemodynamic resolution of shock, evidence of biliary stasis with increased bilirubin and alkaline phosphatase can develop, even though the patient is otherwise improving. Postshock MODS involves similar hepatic pathology.

HEMATOLOGIC SYSTEM

Hematologic manifestations of circulatory shock tend to depend on the nature of shock. Disseminated intravascular coagulation (DIC), characterized by microangiopathic hemolysis, consumptive thrombocytopenia, consumptive coagulopathy, and microthrombi with tissue injury, is most commonly seen in association with septic shock. Because it is due to simultaneous systemic activation of coagulation

and fibrinolysis cascades, it can be differentiated from the coagulopathy of liver failure by determination of endothelial cell-produced factor 8 (normal or increased with hepatic dysfunction). In the absence of extensive tissue injury/trauma, hemorrhagic shock is rarely associated with DIC.²⁹⁷ Dilutional thrombocytopenia is the most common cause of coagulation deficits after resuscitation for hemorrhage.²⁹⁸

METABOLIC ALTERATIONS

Metabolic alterations associated with shock occur in a predictable pattern. Early in shock, when hemodynamic instability triggers compensatory responses, sympathoadrenal activity is enhanced. Increased release of ACTH, glucocorticoids, and glucagon and a decreased release of insulin results in glycogenolysis, gluconeogenesis, and hyperglycemia.^{281,299} An increased release of epinephrine results in skeletal muscle insulin resistance sparing glucose for use by glucose-dependent organs (heart and brain). Late in shock, hypoglycemia may develop, possibly due to glycogen depletion or failure of hepatic glucose synthesis. Fatty acids are increased early in shock but fall later as hypoperfusion of adipose containing peripheral tissue progresses. Hypertriglyceridemia is often seen during shock as a consequence of catecholamine stimulation and reduced lipoprotein lipase expression induced by circulating TNF α .²⁹⁹ Increased catecholamines, glucocorticoids, and glucagon also increase protein catabolism, resulting in a negative nitrogen balance.²⁹⁹

IMMUNE SYSTEM

Immune dysfunction, frequent during and after circulatory shock and trauma, rarely has immediate adverse effects but likely contributes to late mortality. Underlying mechanisms of immune dysfunction include ischemic injury to barrier mucosa (particularly of the gut), leading to anatomic breaches (colonic ulceration) and potential mucosal translocation of bacteria and bacterial products; parenchymal tissue injury due to associated trauma, inflammation, ischemia or free radical injury; and direct ischemic or mediator (immunosuppressant cytokines, corticosteroids, prostaglandins, catecholamines, endorphins)-induced dysfunction of the cellular and humoral immune systems.^{300,301} In particular, macrophage function is adversely affected during trauma and circulatory shock. A decrease in antigen presenting ability impairs the activation of T and B lymphocytes. Associated with this defect are a decrease in Ia antigen expression, a decrease in membrane IL-1 β receptors, and the presence of suppressor T-lymphocytes. Phagocytic activity of the reticuloendothelial system is also compromised, partially due to an acute decrease in fibronectin levels. Suppression of T lymphocyte immune function is manifested by decreased responsiveness to antigenic stimulation and a decreased helper:suppressor ratio. Decreased production of IgG and IgM suggests B cell suppression. Non-specific immune suppression is expressed as decreased neutrophil bactericidal function, chemotaxis, opsonization, and phagocytosis.

Resuscitation agents used in shock may also substantially depress immune function. For example, red blood cell transfusion used in traumatic hemorrhagic shock and in support of oxygen transport in septic shock³⁰² has been shown to suppress immune function and lead to increased

infections (and improved allograft survival).^{303,304} Similarly, dopamine, used for hemodynamic support in shock, has been shown to suppress pituitary production of prolactin (required for optimal immune function), thereby suppressing T-cell proliferative responses.³⁰⁵ Thus, dopamine may contribute, along with stress-induced increases in immunosuppressive glucocorticoids, to T-cell anergy seen in critically ill patients.

All of these factors may contribute to the propensity of critically ill patients to develop ongoing organ system dysfunction as well as a variety of infections during the post-shock phase. It is notable that one third to one half of patients with shock die late in their course following resolution of the acute shock phase.

DIAGNOSTIC APPROACH AND EVALUATION

Shock is always a life-threatening emergency. Diagnosis, evaluation, and management must often occur virtually simultaneously. The diagnosis must be made as early as possible while shock is well compensated. Once marked hypotension and hypoperfusion are present, mortality increases. Because early recognition and treatment are key to survival, the diagnosis is primarily a clinical one. Laboratory and imaging studies are useful for confirming the diagnosis and determining the specific shock etiology. However, therapy of shock should never be delayed in order to accommodate these studies. The initial diagnosis of shock can and should be made strictly on clinical signs and symptoms.

Because shock is the common end point of a variety of insults, evaluation and management for all forms of shock involve a common approach (Box 21.4).

CLINICAL EVALUATION

Impending shock is characterized by the typical compensatory response to cardiovascular stress. Tachycardia, tachypnea, and oliguria (<0.5 mL/kg/h) are usually present. Cool extremities are seen in hypodynamic shock. The blood pressure may be elevated or normal with maximal sympathetic stimulation. With progression, however, blood pressure falls, whereas pulse pressure narrows (except in the case of distributive shock). Frank hypotension (mean arterial pressure <60 to 65 mm Hg in adults) may ensue. The chronic level of blood pressure must be considered. Normotension in a normally hypertensive patient may denote a critical degree of hypoperfusion. With further progression anuria may develop, extremities may become mottled and dusky (except in distributive shock), and the sensorium may become clouded. It is important to note that clinical parameters can underestimate initial resuscitative requirements in critically ill subjects including those with septic shock.³⁰⁶⁻³⁰⁹

Other clinical manifestations of shock are useful for attempting to differentiate the etiology. Hypovolemic shock is characterized by decreased jugular venous pressure. Cardiogenic shock may evidence elevated jugular venous pressure with hepatojugular reflux, an S3, an S4, and regurgitant heart murmurs. Obstructive shock signs usually depend on the nature of the obstruction. Pulmonary embolus may be characterized by dyspnea and right-sided evidence of heart

Box 21.4 General Approach to Shock: Initial Diagnosis and Evaluation

failure. Cardiac tamponade may demonstrate Kussmaul's sign, a pulsus paradoxus and distant heart sounds. Septic shock in the absence of neutropenia usually exhibits a focus of infection along with fever, chills, and warm extremities. Patients with septic shock and neutropenia often have no clinically apparent focus. Elderly patients may present with little more than unexplained hyperventilation and hypotension.

LABORATORY STUDIES

Laboratory data are used to confirm the diagnosis of shock and to help clarify the etiology. Leukocyte count is frequently elevated early in shock due to demargination of neutrophils. Leukopenia may be found in sepsis and late shock. Hemoglobin concentration is variably affected depending on the etiology of shock. For example, nonhemorrhagic hypovolemic shock and septic shock with extravasation of intravascular water to the interstitium may result in an apparent erythrocytosis. Platelet count increases acutely with the stress of circulatory shock, but with progression of sepsis or resuscitation of massive hemorrhage, thrombocytopenia may occur. Arterial blood gases and electrolytes may

demonstrate a nonanion gap acidosis if hypovolemic shock is associated with excessive diarrhea and metabolic alkalosis if associated with vomiting. An anion gap acidosis, often due to elevated levels of lactic acid, usually reflects prolonged inadequate tissue perfusion. Serum creatinine and blood urea nitrogen (BUN) are rarely changed after the acute onset of shock, even if renal injury is present. With slower onset of shock—for example, in sepsis—increased creatinine is common and early resolution is an excellent marker of effective resuscitation and survival. Markers of renal function can also be helpful diagnostically. An isolated increased BUN with anemia and normal creatinine may suggest gastrointestinal bleeding. An arterial blood gas will help to determine the adequacy of oxygenation and give evidence of acid base disturbances. An electrocardiogram (ECG) is critical for the diagnosis of ischemic cardiac injury either as a primary cause of cardiogenic shock or secondary to hypotension associated with shock of another etiology.

Lactate levels (particularly serial determinations) are of use in assessment of prognosis. Substantial data suggest that lactate levels, as a marker of tissue oxygen debt, can predict outcome in shock.^{45,46,310-314} The utility of lactate assessment is limited by the fact that it is a relatively late marker of tissue hypoperfusion.^{315,316} Significant tissue ischemia and injury are present by the time it is elevated. In addition, the liver clears lactate. Liver failure may markedly increase elevated lactate levels during hypoperfusion. Conversely, normal hepatic clearance may obscure limited lactate production by ischemic tissues. Glycolysis and alkalosis will also nonspecifically increase lactate levels.^{317,318} However, since in the appropriate setting, arterial lactate levels beyond 2 mEq/L are associated with increased mortality,^{46,50,312,313,319} such levels should be considered to represent tissue ischemia in the absence of another clearly defined etiology. The adequacy of resuscitation of shock can also be assessed using serial changes of systemic lactate.^{314,319,320} Resolution of elevated lactate, however, may lag following the implementation of effective resuscitation.³²¹

Central venous oxygen saturation can also be used to assess the prognosis and efficacy of resuscitation in shock states including septic shock.^{302,309,322,323} However, central venous saturation, which has been suggested to represent a reliable marker of resuscitation efficacy in sepsis,³⁰² does not appear to correlate well with lactate clearance in some sepsis studies, perhaps reflecting elements other than oxygen debt in those conditions.³²⁰ Poor correlation with mixed venous oxygen saturation has also been noted in septic shock.³²⁴

IMAGING

A chest radiograph is useful in ruling out pneumonia as a source of septic shock, pulmonary edema as a manifestation of cardiogenic shock, tension pneumothorax, pericardial tamponade, and so on. Although abdominal views may be helpful on occasion, intra-abdominal processes resulting in shock are usually clinically apparent. Computerized axial tomograms may be helpful in directing management in specific instances (occult internal hemorrhage, aortic dissection, pulmonary embolus). Similarly, transthoracic and transesophageal echocardiography can diagnose with great accuracy the specific repairable cardiac or aortic lesions associated with shock and can be highly suggestive of other

important diagnoses including hemodynamically significant pulmonary embolus. Pulmonary perfusion scans are useful for confirming massive pulmonary embolism. Other imaging modalities have less of a role in the evaluation of acute shock.

INVASIVE HEMODYNAMIC MONITORING

All patients suspected of having circulatory shock should have an indwelling arterial pressure catheter placed. Blood pressure assessment by manual sphygmomanometry or automated noninvasive oscillometric techniques may be inaccurate during shock due to marked peripheral vasoconstriction.³²⁵ In addition, neither technique supplies continuous monitoring of the rapidly changing hemodynamic status of unstable patients. Further, an arterial catheter allows ready access for arterial blood gas samples and other laboratory tests. In most cases, a peripheral site, such as the radial artery, is utilized. However, given the potential for disparity of pressures between central and peripheral sites,³²⁶ if marked peripheral vasoconstriction due to either sympathetic stimulation or exogenous catecholamines obscures the peripheral pulses, a central site such as the femoral artery may be preferred.

Central venous pressure monitoring is frequently used during the perioperative period to assess the intravascular volume status in patients without critical illness. Because of the relatively stable hemodynamic status of these patients and the questionable benefit of pulmonary artery catheterization in these patients, such an approach is adequate. Similarly, CVP monitoring for otherwise healthy patients being resuscitated for hypovolemic shock may provide useful data. In the appropriate clinical context, CVP monitoring may also occasionally be useful in differentiating among different forms of shock (e.g., low CVP in hypovolemic shock, high CVP in cardiac tamponade). As a rule, though, CVP monitoring is inadequate for the hemodynamic assessment of critically ill patients, particularly those with shock. A number of studies have conclusively shown that central venous pressure does not accurately estimate left ventricular preload in critically ill patients.^{327,328}

The use of the flow-directed balloon-tipped pulmonary artery catheters with thermodilution cardiac output determination capability has been the standard of practice for the hemodynamic assessment of circulatory shock. Their use is supported by a number of studies that demonstrate that experienced physicians cannot accurately determine cardiac filling pressures or cardiac output based on clinical evaluation alone.^{329,330} In addition to cardiac output determination, pulmonary artery catheters provide continuous monitoring of central venous and pulmonary artery waveforms and pressures. Pulmonary artery occlusion pressure (as an estimate of left ventricular end-diastolic pressure and volume) and waveform can be obtained intermittently. Waveform analysis may be useful in cardiovascular diagnoses of cardiac tamponade, restrictive cardiomyopathy, congestive heart failure, ventricular hypertrophy, and mitral or tricuspid regurgitation. These devices also allow withdrawal of blood from the pulmonary artery, enabling the determination of MVO_2 in order to verify sufficient oxygen delivery during hypodynamic shock. In addition, they can demonstrate evidence of right heart and pulmonary artery oxygen

saturation “stepups” for the diagnosis of left-to-right shunts associated with cardiac anatomic abnormalities such as ventricular septal defect. In shock, the flow-directed balloon-tipped pulmonary artery catheter is useful for etiologic classification, determination of optimal management, and to follow the response to therapy. Typical hemodynamic profiles of different forms of shock have been described in Table 21.1.

The utility of pulmonary artery catheterization has been questioned. In a case-matched study, researchers suggested that increased resource utilization and mortality were associated with the use of pulmonary artery catheters in the ICU.³³¹ A series of randomized studies performed since then have reported on the role of the pulmonary artery catheter (PAC) in the setting of major noncardiac surgery,³³² congestive heart failure (CHF),³³³ sepsis and adult respiratory distress syndrome (ARDS),³³⁴ acute lung injury,³³⁵ and in the general ICU setting.^{336,337} In the perioperative management of patients undergoing major noncardiac surgery, the use of a PAC did not impact mortality and was associated with a greater incidence of pulmonary embolism.³³² In critically ill patients diagnosed with CHF, management directed with the use of a PAC did not influence mortality but resulted in more in-hospital adverse events.³³³ Another study comparing the use of a PAC versus central venous monitoring in acute lung injury found no difference in organ failure or mortality.³³⁵ A large trial evaluating the role of the PAC in the management of patients with ARDS secondary to sepsis also found no significant differences in mortality if a PAC was utilized or not.³³⁴ Two randomized studies of general ICU patients similarly concluded that the use of PAC among critically ill patients neither increased nor decreased mortality.^{336,337} Most, although not all, meta-analyses have shown no consistent benefit with the PAC.³³⁸⁻³⁴¹ These studies failing to show a lack of clinical benefit have been paralleled by other studies questioning some of the basic premises of PAC utility. Several studies have shown a lack of correlation between PAOP/CVP and ventricular volumes in the critically ill.^{342,343} One study has even demonstrated that PAOP and CVP fail to predict ventricular filling volume, cardiac performance, or the response to volume infusion in normal volunteer subjects.³⁴⁴ Despite these data, no studies have examined the use of pulmonary artery catheters in cases of shock specifically. Nonetheless, the use of the PAC in the United States has decreased dramatically since the 1990s.³⁴⁵

One parameter that a pulmonary artery catheter uniquely provides is mixed venous oxygen saturation. This measure may assess the adequacy of resuscitation of low output states prior to the presence of anaerobic metabolism (as signified by increased lactate). MVO_2 rises with increases of perfusion above requirements and falls, with increasing oxygen extraction ratio, as perfusion becomes inadequate (Fig. 21.3). Normal MVO_2 falls within the 65% to 75% range. During myocardial infarction, saturations of less than 60% are found with congestive heart failure, and less than 40% with cardiogenic shock.³²³ Lactate accumulation and supply-dependent oxygen consumption begin to appear as saturation levels fall below 30% to 40%.^{346,347} MVO_2 is especially useful in determining whether low cardiac outputs indicate supply-dependent oxygen consumption (MVO_2 low) or normally depressed metabolic demands (normal MVO_2). Due to the maldistribution of perfusion in distributive shock (or

Figure 21.3 Oxygen supply–dependent oxygen consumption in shock. Physiologic supply–dependent oxygen consumption is characterized by a biphasic relationship between oxygen delivery ($\dot{D}O_2$) and oxygen consumption ($\dot{V}O_2$). The inflection point defines the physiologic critical oxygen delivery ($\dot{D}O_{2crit}$). Below this $\dot{D}O_{2crit}$, $\dot{V}O_2$ is linearly dependent on $\dot{D}O_2$, the oxygen extraction ratio is maximal, and lactate (indicating anaerobic metabolism) is produced. Above the physiologic $\dot{D}O_{2crit}$, $\dot{V}O_2$ is independent of $\dot{D}O_2$, the oxygen extraction ratio varies to maintain a constant $\dot{V}O_2$, and lactate is not produced.

substrate utilization defect in septic shock) and left-to-right shunting in cardiogenic shock associated with ventricular septal defects, $\dot{M}\dot{V}O_2$ is not useful in assessment in those conditions. Central venous oxygen saturation (cSV_{O_2}) has been proposed as an alternate way to examine the adequacy of resuscitation.^{302,309}

Oxygen delivery and oxygen consumption variables can also be determined using pulmonary artery catheter–derived data. Although such global perfusion data appear to have prognostic significance for large groups of the critically ill, their utility is controversial when applied to individual patients.

Modifications to the standard pulmonary artery flotation catheter allow continuous monitoring of $\dot{M}\dot{V}O_2$ or determination of right ventricular ejection fractions and volumes. Although both innovations have been utilized for clinical research purposes and each theoretically offers unique insights into shock, they have no defined role at this time in clinical shock management.

ANCILLARY MONITORING TECHNIQUES

OXIMETRY

Because oxygen delivery is dependent on arterial oxygen saturation, pulse oximetry should, in theory, provide useful data during circulatory shock. However, limitations of the

technique include the fact that ambient light sources, dys-hemoglobinemias (methemoglobin, carboxyhemoglobin), lipemia, and hypothermia can affect results.³⁴⁸ Motion artifact may generate a false signal.³⁴⁹ Shock-associated vasoconstriction also impairs signal acquisition. One study has shown that a cardiac index less than 2.4 L/min/m² is associated with signal loss.³⁵⁰ Although these problems limit the utility of pulse oximetry in the acute management of circulatory shock, the technique may be more helpful during postresuscitation monitoring. At this time, sequential arterial blood gases provide more reliable data during acute shock.

Transcutaneous and transconjunctival oxygen tension measurement are newer noninvasive techniques used for determining tissue oxygen tension, which show some promise in the management of patients at risk for or following the resuscitation of circulatory shock. In the absence of shock, transcutaneous probes reflect arterial oxygenation.³⁵¹ A number of studies, however, have suggested that if arterial oxygen tension is stable, the devices may be of use in assessing global or regional changes in perfusion and oxygen metabolism.³⁵²⁻³⁵⁵ Global hypoperfusion due to low output shock (as well as local vasoconstriction) results in decreased transcutaneous oxygen tension and a decreased ratio of transcutaneous to arterial oxygen tension.³⁵³ Decreased transcutaneous oxygen tension, seen early in hemorrhagic shock, may precede hypotension.^{354,355} Decreases in transconjunctival oxygen tension predict hemodynamic collapse in perioperative patients³⁵² and death in patients with cardiogenic shock.³⁵⁵ Transcutaneous and transconjunctival measurement of oxygen tension may also be useful in assessing the adequacy of tissue perfusion during resuscitation from hypodynamic shock.^{356,357}

As anaerobic glycolysis with lactate generation is paralleled by the production of hydrogen ions during hypodynamic shock, noninvasive measurement of tissue pH may provide an attractive, metabolism-based assessment of adequacy of tissue oxygenation/perfusion. Because the stomach is easily accessible, may reflect overall splanchnic perfusion during shock,³⁵⁸ and splanchnic perfusion is known to be altered early in shock,³⁵⁹ most clinical work has focused on gastric mucosal pH. Studies suggest that gastric intramucosal pH correlates closely with systemic and organ oxygen consumption, organ failure, and outcome in critically ill humans.^{360,361} Normalization of gastric mucosal pH has been suggested as one appropriate target during resuscitation of circulatory shock.³⁶² Limited evidence suggests such an approach may be associated with improved survival.³⁶³ However, further supportive studies are required before this can be accepted as an appropriate therapeutic target.

Near infrared spectroscopy (NIRS) is an innovative technique able to noninvasively monitor regional tissue blood flow, oxygen delivery, and oxygen utilization. Although several investigators have claimed the ability to examine mitochondrial oxidation state (particularly the redox state of cytochrome aa3, the terminal portion of the electron transport chain), these measurements may actually reflect only tissue oxygenation.

Normal tissue oxygenation is the ultimate expression of normal cardiopulmonary function. Any major perturbation of cardiopulmonary status including incipient shock should ultimately express decreased tissue oxygenation. Because peripheral tissue perfusion is, as part of normal

compensatory mechanisms, among the first to become restricted during cardiovascular stress, peripheral tissue oxygenation may serve as an excellent marker of cardiovascular stress. Near-infrared light is known to pass through biologic tissues such as skin and muscle. By illuminating a tissue with a known amount of incident light, the amount recovered depends on the degree of absorption by chromophores within the tissue and the amount of scattering. Only three chromophores are known to absorb light in the near-infrared wavelength spectrum: hemoglobin, myoglobin, and cytochrome aa3. All three are known to vary their absorption of near-infrared light depending on whether they are in an oxygenated or deoxygenated/reduced state. By monitoring these parameters, NIR spectroscopy is a unique tool that allows for real-time assessment of the adequacy of tissue perfusion during both the resuscitation and ongoing management of patients with shock. Studies in both animals and humans have suggested the potential utility of this technique in assessment of shock including hypovolemic/traumatic³⁶⁴⁻³⁶⁹ and septic.^{370,371}

The application of advanced echocardiography techniques to the ICU environment as intermittent monitoring tools may represent one of the most exciting developments in critical care management. A number of factors have hastened this development. These include questions regarding the safety and efficacy of routine pulmonary artery catheter utilization; the availability of relatively inexpensive, portable echocardiography systems; the application of advanced software algorithms to analyze data; and the development of new, high-resolution echocardiographic techniques including transesophageal and contrast echocardiography. The confluence of these factors has resulted in a substantial increase in the use of echocardiography in the ICU assessing hemodynamic instability and shock. In addition to its long-recognized ability to detect anatomic lesions (pericardial tamponade, pericardial effusion, septal defects, valvular disease, aortic dissection), new techniques allow for the assessment of cardiac output, stroke volume, preload (ventricular volumes), intravascular volume status (inspiratory inferior caval collapse), pulmonary artery pressures, systolic contractility (ejection fraction), diastolic function, and regional motion abnormalities at baseline and under stressed conditions.³⁷² The utility for diagnosis of hemodynamically significant pulmonary embolism has also been established.³⁷³ The widespread dissemination of echocardiographic skills among the next generation of intensivists has allowed for a substantial reduction in the use of invasive monitoring techniques including pulmonary artery catheterization.

MANAGEMENT AND THERAPY

Patients suspected to be in circulatory shock should be managed in an intensive care unit with continuous ECG monitoring and close nursing support. Those whose etiologic diagnosis is in doubt, whose hemodynamic instability does not quickly resolve with intravenous fluids, or who are medically complicated should undergo invasive hemodynamic monitoring with arterial and pulmonary artery catheters. Laboratory tests, as mentioned earlier, should be performed at or before admission.

Management of shock can be divided into specific therapy for the triggering injury and general therapy of the shock syndrome. Examples of specific therapy include antibiotics and drotrecogin-alfa (activated) for treatment of septic shock, blood transfusion for hemorrhagic shock, thrombolysis for acute myocardial infarction or massive pulmonary embolus, and pericardial aspiration for pericardial tamponade. Specific therapy for different etiologies of shock will be discussed in their separate chapters.

AIMS

Because the shock syndrome shares many characteristics across different etiologies, the general management of shock is similar in all cases. The basic goal of circulatory shock therapy is the rapid restoration of effective perfusion to vital organs and tissues prior to the onset of cellular injury. Because effective tissue perfusion depends on both sufficient cardiac output and adequate driving pressure, therapy of shock requires maintenance of an appropriate cardiac index and mean blood pressure (Box 21.5). However, because for brief periods marked hypoperfusion is better tolerated than severe hypotension, the first specific resuscitative aim, support of blood pressure (>60 to 65 mmHg in a baseline normotensive patient), may initially take priority over the second specific aim, maintenance of cardiac index. Finally, maintaining perfusion sufficiently high that arterial lactate concentration remains under 2.2 mmol/L is a generally accepted approach to avoiding anaerobic metabolism and ischemic tissue injury (see Box 21.5). The practice of targeting oxygen delivery to specified supranormal oxygen delivery goals or to evidence of supply-independent oxygen consumption in the ICU has been substantially discredited by clinical studies.³⁷⁴⁻³⁷⁷ However, early targeting (<6 hr post presentation) to a central venous oxygen saturation (cSVO₂) of >70% using a defined protocol with fluids, blood transfusion, and dobutamine support has been shown to improve outcome in severe sepsis and septic shock.³⁰² This approach has not been validated in other forms of shock.

Box 21.5 General Approach to Shock: Immediate Goals

Hemodynamic

- MAP > 60 to 65 mmHg (higher in the presence of coronary artery disease)
- CVP = 8 to 12 mmHg/PAOP = 12 to 15 mmHg (may be higher for cardiogenic shock)
- CI > 2.1 L/min/m²

Optimization of Oxygen Delivery

- Hemoglobin > 9 g/dL; > 7 g/L postshock is sufficient
- Arterial saturation > 92%
- MV_O₂ > 60%, sCVO₂ > 70%
- Normalization of serum lactate (to < 2.2 mM/L)

Reverse Organ System Dysfunction

- Reverse encephalopathy
- Maintain urine output > 0.5 mL/kg/hr

It is of note that one of the major achievements in shock therapy since the early 2000s has been the recognition that the speed of implementing supportive and specific therapies may be critical to an improvement in outcomes. This concept of a “golden hour” has long been recognized in the context of specific and resuscitative therapy of trauma-induced hypovolemic shock with blood products and surgical management^{378,379} and then cardiogenic shock due to myocardial infarction with emergent primary angioplasty or thrombolysis.³⁸⁰ A similar rapid treatment paradigm has been established for thrombolytic therapy for obstructive shock due to massive pulmonary embolus.^{78,79,381} Similarly, rapid fluid resuscitation (<6 hours)³⁰² and antimicrobial therapy (<1 hour)¹⁰⁷ have been shown to be key to maximizing survival in cases of severe sepsis and septic shock. The accelerated provision of effective therapy probably accounts for reports of improved clinical outcomes with medical emergency response teams.³⁸²⁻³⁸⁴ Variation in the baseline provision of effective therapy likely accounts for the inconsistent results seen with such teams.³⁸⁵ The importance of early aggressive resuscitative and specific therapy of all shock states cannot be sufficiently emphasized.

RESUSCITATION

The universal basics of resuscitation underlie the initial management of circulatory shock. Because many patients with circulatory shock may have accompanying trauma and a decreased level of consciousness, the ventilatory status of the patient must be secured. This may involve tracheal intubation or mechanical ventilation, if necessary. Oxygen should be provided at a sufficiently high concentration to supply an arterial oxygen saturation of greater than 90% to 92%. Unintubated patients may require high flow (30 to 45 L/min) or rebreathing oxygen delivery systems, as many patients will have unusually high minute ventilation volumes. Intubated patients should initially receive full ventilatory support in order to decrease systemic oxygen demand. Given that pulmonary infiltrates (aspiration, pneumonia, or ARDS) are common, positive end-expiratory pressure (PEEP) may be necessary to ensure adequate oxygenation. Potential adverse hemodynamic effects from positive pressure ventilation (related primarily to decreased venous return) may be seen but can be minimized by fluid loading so that the patient is euvolemic or modestly hypervolemic.

Depending on the clinical situation, pain management may be necessary. Again, potential adverse hemodynamic effects may be seen if intravascular volume is inadequate because all measures result in some degree of venodilatation either directly or by decreasing sympathetic tone. Two- to 4-mg intravenous boluses of morphine are recommended. During circulatory shock, clearance of morphine by the liver may be impaired due to hepatic hypoperfusion. Besides relieving pain, analgesia should also decrease systemic oxygen consumption.

Management of lactic acidosis developing during circulatory shock is problematic. Bicarbonate therapy may have adverse effects on intracellular pH even while improving the pH of the extracellular fluid. Further, even when pH is extremely low, bicarbonate therapy does not improve systemic hemodynamics in shock associated with acidosis.³⁸⁶ In addition, increasing serum pH may adversely affect

the oxyhemoglobin dissociation relationship. The optimal approach to the management of lactic acidosis is to improve organ and systemic perfusion so that anaerobic metabolism is limited and the liver and, to a lesser extent, kidneys can clear the accumulated lactate. If this is not effective, restricting the use of sodium bicarbonate to situations in which pH is less than 7.1 to 7.15 may be appropriate.

Initial management of circulatory shock should almost always include a crystalloid fluid challenge. In the absence of invasive monitoring with a pulmonary artery catheter, the only practical exception is if clinical evidence strongly suggests ventricular filling pressures are already elevated. This is usually limited to clinical situations involving cardiogenic shock and marked pulmonary edema. Even then, if pulmonary edema is manageable, crystalloid challenge may be appropriate. The volume of the challenge is variable. Large volumes, on the order of 1 to 2 L given rapidly (0.5 to 1 L every 10 to 15 minutes), are frequently used in hemorrhagic and septic shock. One hundred- to 200-mL boluses may be used during cardiogenic shock. If shock does not resolve promptly after the initial fluid challenge, patients should undergo a more detailed invasive (central venous catheter) or noninvasive (echocardiographic) assessment. As previously discussed, a central role for pulmonary artery catheterization in shock is now questioned and highly controversial.

Although aggressive fluid resuscitation is well accepted in the therapy of shock, emerging data support more limited resuscitation in some contexts. Resuscitation to hypotensive targets (target systolic blood pressure 80 to 100 mmHg) has been recommended in hemorrhagic shock due to penetrating trauma based on data showing improved survival using this approach.^{387,388} In addition, a limited fluid resuscitation protocol for 7 days has been shown to improve the number of ventilator- and ICU-free days in acute lung injury without increasing the prevalence of shock or the mortality rate.³⁸⁹ A more limited early fluid resuscitation has also been shown to be associated with improved survival in children with shock associated with infection in under-resourced settings.³⁹⁰

In addition, substantial controversy exists regarding the appropriate use of crystalloid and colloid fluids after initial resuscitation attempts. The basis of this controversy lies with the differing oncotic properties of the fluids. Crystalloid fluids (such as normal saline and lactated Ringer's solution) contain sodium chloride in a quantity that closely matches extracellular fluid. No large molecules are present. Thus, such fluids distribute into the extracellular space. Colloids, in addition, contain albumin or large osmotically active carbohydrates (hydroxyethyl starch, dextran), which may be held within the intravascular space resulting in an increase of the plasma oncotic pressure. It has been suggested that in shock associated with microvascular changes of permeability (such as sepsis), colloid fluids will remain in the intravascular space, leading to decreased tissue edema and noncardiogenic pulmonary edema.³⁹¹ However, the limited human studies available suggest that although radiographic infiltrates may appear more severe with crystalloid resuscitation of sepsis, gas exchange is comparable to colloid resuscitation.⁴¹

Importantly, it has been proposed that colloids may provide better outcomes in the resuscitation of shock due

to the rapidity and persistence of volume expansion compared to crystalloid infusion.^{41,392} However, clinical studies for the most part have not supported this contention. Meta-analyses have largely failed to demonstrate the clinical outcome superiority of crystalloids compared to either albumin or synthetic colloids.³⁹³ In fact, one meta-analysis of randomized, controlled studies examining the effect of fluid administration in critically ill patients with burn injury, hypovolemia, or hypoalbuminemia suggested increased mortality in patients treated with colloids.³⁹⁴ In one large, randomized study of albumin versus normal saline, a trend toward improved outcomes with albumin in severe sepsis and saline in trauma failed to reach significance.³⁹⁵ More recently, a substantial body of literature has shown that synthetic colloids increase the risk of renal injury and death, particularly in sepsis and septic shock.³⁹⁶⁻³⁹⁸ An increased risk of renal injury/dialysis requirement and risk of death was shown for hydroxyethyl starch versus Ringer's solution therapy in two large randomized trials of sepsis.^{397,398} There are some data, though, that suggest colloid resuscitation may clear lactate more quickly and result in less renal injury than crystalloid in penetrating trauma.³⁹⁹ Given the much higher costs of colloids and the higher risk of renal injury and death with synthetic colloids, resuscitation of shock should generally focus on crystalloid solutions unless speed of resuscitation is paramount (i.e., there is acute major trauma or massive hemorrhage). In those settings, colloidal solutions may be initially favored until blood is available.

With respect to hemoglobin, one randomized trial has suggested that a hemoglobin level of 70 g/L is sufficient for most patients in the ICU (other than those with a high severity of illness or acute coronary syndrome).^{400,401} Although several other studies have pointed out the potential risks associated with blood transfusion in the ICU setting,⁴⁰²⁻⁴⁰⁵ no study has directly examined hemoglobin requirements during shock. The only study to (indirectly) examine blood transfusion in shock suggested that early augmentation of hematocrit to >30% during septic shock as part of a protocol to drive central venous oxygen saturation to >70% was associated with improved survival.³⁰² For that reason, it is reasonable to recommend that a hemoglobin of 90 to 100 g/L be maintained during acute shock.

Once intravascular volume is optimized, the next line of therapy of circulatory shock usually involves inotropes and vasopressors. Alternately, vasopressors may be occasionally required for brief periods of blood pressure support in extremely hypotensive patients prior to the initiation of fluid infusion.

Four major classes of agents are used clinically for inotropic or vasopressor support: sympathomimetics, phosphodiesterase inhibitors, cardiac glycosides, and vasopressin (anti-diuretic hormone) (Table 21.4). Sympathomimetics (catecholamines) may activate cardiac beta-1 and alpha adrenoreceptors, peripheral vascular alpha or beta-2 receptors, and vascular dopaminergic receptors. Cardiac beta-1 adrenoreceptors augment heart rate and myocardial contractility by increasing activity of adenylate cyclase resulting in increased generation of cyclic adenosine monophosphate (AMP).⁴⁰⁶ Alpha receptors act through phospholipase C production of inositol triphosphate and diacylglycerol.⁴⁰⁷⁻⁴⁰⁹ Peripheral vascular alpha receptors cause vasoconstriction, whereas peripheral beta-2 adrenoreceptors induce a mild

vasodilatation. Cardiac alpha adrenoreceptors contribute to increased contractility (but not heart rate) when stimulated.^{407,409} Dopaminergic adrenoreceptors, mediating dilatation, are found in the arterial vessels supplying vital organs (including the heart, brain, kidneys, and splanchnic organs).⁴¹⁰ Phosphodiesterase inhibitors such as amrinone and milrinone augment cardiac contractility by inhibition of cyclic AMP degradation. They also relax vascular smooth muscle.⁴¹¹ Despite a long history of digitalis use in the management of congestive heart failure and data suggesting hemodynamic benefit in sepsis,⁴¹² cardiac glycosides are rarely used for the acute management of circulatory shock due to their narrow therapeutic index and long half-life. Uncontrolled studies have shown that endogenous vasopressin concentrations may be relatively deficient in shock states and that infusion of vasopressin (which has little effect in healthy, normotensive subjects) can have a profound pressor effect during vasodilatory shock.⁴¹³⁻⁴¹⁶

Norepinephrine, an endogenous catecholamine, exerts both powerful inotropic (cardiac alpha and beta-1 adrenoreceptors) and peripheral vasoconstriction effects (alpha adrenoreceptors). It is currently the favored catecholamine for the initial management of shock. It can be used for persistent hypotension despite high-dose dopamine during septic and obstructive shock. It should generally be used only transiently in cardiogenic shock because it may dramatically reduce forward flow. Similarly, it should not be required during hemorrhagic shock except for extremely brief periods of blood pressure support pending volume infusion. Infusion rates of 2 to 20 µg/min are commonly used, but if necessary, higher rates may be tried. Suggestions that there is clinical utility in the concomitant use of "low"-dose dopamine with norepinephrine to generate sparing of pressor and shock-associated renal injury have been refuted.⁴¹⁷⁻⁴¹⁹

Dopamine has fallen out of favor as the initial vasopressor used for circulatory shock. A central and peripheral nervous system neurotransmitter and the biologic precursor of norepinephrine, it stimulates three different receptors: vascular dopaminergic, cardiac β1, and vascular α. In addition, a part of dopamine's myocardial effects is mediated by the release of endogenous norepinephrine. Dose-dependent maximal stimulation of each of dopamine's target receptors has been suggested to result in different typical hemodynamic responses at different infusion rates. At infusion rates of less than 4 to 5 µg/kg/min, dopaminergic effects have been said to dominate, but studies suggest this has little clinical relevance (although in the past it was the theoretical basis for the use of low-dose dopamine for renal protection).^{418,419} Vascular DA2 receptors vasodilate the renal, mesenteric, myocardial, and cerebral vascular beds. In addition, renal DA1 receptors mediate a mild natriuresis.⁴²⁰ β-adrenoreceptor-mediated cardiac inotropic effects have been suggested to dominate at doses below approximately 10 µg/kg/min with α-adrenoreceptor vasopressor effects more prominent at doses over 10 µg/kg/min.⁴¹⁰ It is important to note, however, that dopaminergic and cardiac adrenergic effects are not suppressed at higher doses but rather that additional effects are seen. In addition, there is substantial inter-individual variation in response with some showing substantial vasopressor or inotropic responses at low infusion rates. For management of circulatory shock, dopamine

Table 21.4 Relative Potency of Intravenously Administered Vasopressors/Inotropes Used in Shock*

	Cardiac			Peripheral Vasculature			
	Dose	Heart Rate	Contractility	Vasoconstriction	Vasodilation	Dopaminergic	Typical Clinical Use
Dopamine	1-4 µg/kg/min	1+	1-2+	0	1+	4+	All shock
	5-10 µg/kg/min	2+	2+	1-2+	1+	4+	
	11-20 µg/kg/min	2+	2+	2-3+	1+	4+	
Norepinephrine	2-20 µg/min	2+	2+	4+	0	0	Refractory shock
Dobutamine	1-20 µg/kg/min	1-2+	3+	1+	2+	0	CHF; cardiogenic, obstructive and septic shock
Dopexamine[†]	0.5-6 µg/kg/min	2+	1+	0	3-4+	4+	CHF; cardiogenic shock
Epinephrine	1-8 µg/min	4+	4+	4+	3+	0	Refractory shock or anaphylactic shock
Phenylephrine	20-200 µg/min	0	1+	4+	0	0	Neurogenic or septic shock
Isoproterenol	1-8 µg/min	4+	4+	0	4+	0	Cardiogenic shock (bradyarrhythmia), torsades de pointes, ventricular tachycardia
Vasopressin	0.04-0.10 U/min (start 0.01-0.04 U/min; titrate up 0.02-0.04 U/min every 20-30 min)	0	0	4+	0	0	Vasodilatory (e.g., septic) shock
Milrinone	37.5-75 µg/kg bolus over 10 min; 0.375-0.75 µg/kg/min infusion	1+	3+	0	2+	0	CHF; cardiogenic shock
